Sensory Systems

1 / SENSORY PROCESSES

The adaptation of man to his environment and to the society of his fellow men requires the constant processing of information received from the environment and from individuals within the environment Any form of activity constitutes an interaction process wherein any kind of movement or action produces change The detection of such a change via the sensory systems permits the regulation and control of subsequent actions Much of consciousness, even in the absence of significant sensory inputs, seems to involve sensory imagery We think in terms of visual and auditory imagery and imagery involving the other senses Although in the analytic study of sensory processes there is often a tendency to consider them as independent dimensions, our perception of the environment and our relations to it depend in fact upon many complex interactions of the individual sensory modalities (Gibson, 1966) It is our purpose in the material which follows to consider the various important sensory processes individually for the purpose of understanding their nature, acknowledging the fact that they do not function independently but provide a collective basis for consciousness and the control of our activities

THE RECEPTOR ORGANS

The different sensory modalities are distinguished by specialized receptors which mediate responses to stimuli appropriate for the transfer of information in each of the individual sensory domains Sensory receptors are sometimes divided among each of three classifications, the *exteroceptors*, the *interoceptors*, and the *proprioceptors* The *exteroceptors* respond to stimuli that arise outside of the body, such as the light which stimulates the eye, sound pressure which stimulates the ear, various forms of mechanical pressure or contact with objects of a temperature different from that of the skin which stimulate the receptors of touch, minute quantities of chemical substances which stimulate the olfactory sense organs, and the receptor organs of taste The *interoceptors* lie within the mucous linings of the respiratory or digestive tract and respond to materials ingested or inhaled and to changes in pressure The *proprioceptors* are sensory receptor endings that respond to stimuli generated by muscular movement of the body or changes in muscular tension They reside in skeletal muscle, in tendons, in joints, in the heart, the carotid sinus, and in the gastrointestinal wall The vestibular receptors of the nonauditory labyrinth respond to linear and angular accelerations, that may be imposed upon the passive organism or may be generated by motor acts of the organism These receptors work in close harmony with the proprioceptors of muscle and are sometimes included with this category They are also extremely important in the control of eye movements, however, and hence for visual perception

THE STIMULUS

Classically, the physical form of stimulation that is most natural or appropriate for a given sensory receptor has been called the *adequate stimulus* This terminology has resulted in the use of the term *inadequate stimulus* for many forms of physical stimulation which may excite a given receptor system, but which are not likely to provide stimulation under normal circumstances In this sense then, inadequate stimuli are perfectly adequate to produce a response and the terminology is somewhat confusing In the material which follows we will refer to the *appropriate stimulus* rather than the *adequate stimulus* in order to avoid possible confusion

An extremely important aspect of the study of sensory processes is the definition of the nature of the appropriate stimulus The physical dimensions of the stimulus and the range of energies to which the receptor will respond, when an energetic continuum can be identi-

fied, must be determined in order to understand the nature of the function of peripheral receptor organs

CONSCIOUS CONCOMMITANTS OF SENSATION

The prominence of a sensory dimension in our consciousness varies significantly from one sensory modality to another Prominence can not be assigned any fixed order either, it may vary with circumstances In a normal, awake subject, with a well-lighted environment, the visual domain will normally be of great prominence Obviously, this will not be so if there is no light, if the subject's eyes are for some reason covered or closed, or if the subject is blind The auditory dimension may or may not be prominent, depending on the level of stimulation For someone listening with concentration to a musical work or engrossed in a conversation, the auditory dimension may be more prominent than the visual For someone engaged in any form of athletic competition which involves complex movements of the body, the vestibular sense will be playing an extremely critical role under normal conditions but will have no conscious concommitant which can be uniquely associated by the individual with that sensory dimension The same may not be true for organisms other than man in which vestibular function is more important These include flying birds, arboreal creatures and fish, animals with much greater mobility in three dimensions than man has Olfactory and gustatory senses may be prominent under certain circumstances, but their prominence tends to be relatively infrequent and associated with such actions as eating and exposure to unusual sources of stimulation Other classes of receptors that respond to chemical stimuli, those in the carotid sinus and the aortic bodies, afford an important basis for control of physiological processes but never intrude into consciousness Receptors for the sensation of pain, whether they reside in the skin or deeper within the bodily structure, can provide a compelling conscious component of sensation but, fortunately, under normal circumstances they are relatively inactive Their role is usually a protective one in providing information to assist the organism in removing itself from sources of potential injury

Although it is convenient to think of the senses categorically, it is most important to recognize that our perceptions of the physical world in which we live are dependent upon multisensory inputs and interactions among the senses Thus, the interpretation of visual stimuli may frequently be influenced by vestibular stimuli, proprioceptive stimuli and possibly auditory stimuli The developing organism learns to expect certain correlations among different stimulus dimensions As we shall see, certain unique situations which may result in a noncorrespondence of different stimuli with expected relationships may be extremely disconcerting or even debilitating Such noncorrespondences may be encountered between visual and vestibular inputs during exposure to the motions of a ship on a heavy sea or the complex flight path of a maneuvering aircraft Noncorrespondence between visual and tactual or muscle senses may arise during attempts to move about in a "distorted room" of the type one may find in an amusement park

METHODS OF STUDYING SENSORY SYSTEMS

Psychophysical Studies. The mode of functioning of sensory processes has fascinated man for hundreds of years and he has devised an ingenious variety of methods for their study For any situation where a human subject can detect stimulation of a given sense receptor, the function of the receptor may be studied with the intact human organism as an indicator of the effect of stimulation It is thus possible to explore the appropriate stimulus in terms of its physical dimensions along various continua In the case of vision, the subject's task may simply be to indicate when he is able to detect the presentation of a stimulus The investigator may then explore such variables as the wavelength of the stimulus, its physical intensity, the region of the retina on which the stimulus is projected, the size of the stimulus, and the temporal duration of its exposure Obviously, these various dimensions may be expected to interact and their interactions can also be studied The results of many such investigations of the visual sensory system are documented in the chapter on vision Similar investigations of the physical dimensions of the stimulus have been carried out for hearing,

touch, and the acceleration forces which stimulate the vestibular mechanism It is not possible to isolate physical continua associated with olfactory and gustatory stimulation, and so investigations of these senses have not been organized around the physical dimensions of the stimulus Rather, investigators have attempted to catalog and look for similarities among chemical stimuli which provide similar qualitative experiences in these sensory dimensions In addition to the minimum required physical energy, or concentration of a chemical substance, necessary for the threshold detection of stimulation, the investigator may wish to explore the effect of increasing stimulation along an intensive or concentration dimension and note the effect on the subject Limits of stimulation may be defined at which pain is experienced, or further increase in the appropriate dimension of the stimulus is accompanied by no further increase in the subjective intensity of the sensation Such studies may be carried out by having subjects adjust a matching stimulus to the experimental stimulus or by requiring them to make a subjective rating of stimulus intensity Philosophical objections may be raised in connection with the latter procedure, but various rating techniques have provided quite consistent results when properly used (Stevens and Galanter, 1957)

Electrophysiological Studies. Studies of sensory systems with human subjects possess certain important limitations It is difficult to decide what part of the overall sensory system may be determining the response to stimulation For example, is the maximum audible frequency which can be discriminated by man limited in the peripheral receptor for hearing or somewhere between the receptor and the cortical centers involved in hearing? It has been possible in man to record electrical activity arising directly in the retina as a result of photic stimulation Such activity, recorded as the electroretinogram, permits the limited study of purely peripheral processes in the visual system of man Unfortunately, similar indices of peripheral activity are not readily available for the other sensory systems

Sensory processes may be studied in animals with measurement of response at any desired point within the nervous system Techniques have been developed for the insertion into single cells of tiny electrodes with tip diameters even smaller than 1 μ when necessary In the visual system, in at least one organism, intracellular recordings have been obtained from each of the known cell types of the retina (Dowling, 1970) Electrodes need not be inserted into a cell in order to record the activity of a single cell Relatively small electrodes, with tip diameter of from 1 to 5 or more μ, located in the vicinity of a single cell or a single fiber may pick up signals which reflect the activity of that cell or fiber alone The higher the impedance of the electrode, the better is its discrimination With the higher impedance, however, it may be somewhat more difficult to make an initial detection of the activity of any cell

Sensory Coding. In recent years, studies of the activity of single cells and single fibers in the sensory nervous system have provided important new insights into the nature of sensory function It has become apparent that as sensory information is transmitted from the primary receptor through the various neural elements which link the receptor to cortical centers for the mediation of sensory response, there is a kind of selective convergence from certain receptors such that cells higher in the nervous system may respond selectively to unique characteristics of the stimulus dimension (Barlow, 1969) For example, there are cells in the cortex of higher animals which respond to a moving stimulus with a certain orientation in the visual world In hearing, specific cells may respond to certain patterns of change in the frequency or intensity of an auditory stimulus Others may respond maximally when a stimulus is presented to one ear shortly before it is presented to the other, as is the case for a sound source located on one side of the sensing organism Such cells selective to the sequence of lateral stimulation have even been reported for the olfactory system It thus appears that the nervous system is abstracting out certain dimensions of the stimulus world In some way the brain succeeds in putting these dimensions back together in a fashion that permits us to achieve veridical perceptions of the world in which we live

Animal Research Animals offer the advantage of permitting the study of the action of sensory systems at any location along the way from the primary receptor to the highest cortical centers identified for a given sensory system Such studies may involve microelec-

trodes as described above, or more gross electrodes that mirror the activity of relatively large populations of cells Both types of investigation are of value The procedure to be preferred depends upon the nature of the questions an experimenter wishes to ask

It may seem reasonable to study overall sensory experience in human subjects and to examine various portions of sensory systems electrophysiologically in animals The latter work may provide an understanding of why it is that certain results are obtained with the human subject for stimulation of a given sensory dimension There are serious objections however, to extrapolating from electrophysiological studies of animals directly to the intact human Certain electrical signals recorded in a sensory system may be merely incidental to stimulation, a kind of by-product of the significant aspects of the process, and hence not a direct linking process in the overall function of the sensory system The cochlear microphonic potential, discussed in some detail in the chapter on hearing, is probably such an incidental effect Another serious problem rests with the fact that the sensory processes of animals are not identical to those of the human In recent years, highly significant differences in the way in which visual information is processed in the sensory systems of fish, frogs, birds, rabbits, cats, and monkeys have been revealed

Presumably, the closer to man phylogenetically the experimental animal under study, then the more valid may be extrapolations from electrophysiological studies of that animal to the sensory processes of man Students of sensory systems however, have not been content with this kind of reasoning Another approach is to study the whole animal just as man himself is studied in sensory experiments The animal cannot verbalize his responses, but he can be trained to respond affirmatively or negatively if the experimenter provides him with an adequate reason to do so The reason may be a food reward or the avoidance of a shock or a few drops of water or some other appropriate *reinforcement* for a correct response Studies then can be conducted in which animals will signal appropriately if they detect a stimulus If, in behavioral studies of sensory processes with animals, the results are similar to, or identical with those found in man, it is more reasonable to assume that the underlying physiological processes studied by means of electrical recording techniques may be the same as those which exist in man

Even in animals that may be difficult to train to respond to stimulation, behavioral studies can be conducted This is accomplished by employing some natural reflex with which the animal is already equipped to respond to certain stimulus dimensions A favorite reflex for the study of visual processes has been the optokinetic reflex This is a tendency for an animal to turn in the direction of motion of a repeating pattern such as vertical stripe The head may turn, the whole body may turn, or the eyes may turn Obviously, if the stripes are not seen because they are too dim or too fine or because the contrast is too low, then the response will not appear

In behavioral studies, it is usual to train an animal to perform some special response when it makes a desired sensory discrimination Some dimension of the stimulus, such as the wavelength of light or the frequency of sound, may then be changed and the threshold for a discrimination redetermined under these new conditions The experimenter assumes that somewhere in the nervous system a criterion event of some sort has occurred which permits the animal to respond appropriately It is probably not true that events within the nervous system are identical for a constant threshold criterion when one alters the dimensions of the stimulus that are known to result in qualitative changes (Zacks, 1970) Nonetheless, this kind of assumption is frequently made and it is the basis for assuming that the results of experiments which explore systematically the influence of changing some stimulus dimension may be plotted as continuous functions when a constant criterion, such as detection threshold, is employed (Brindley, 1960)

In order to compare electrophysiological studies with behavioral studies of this sort, a fixed criterion is also adopted In the case of electrophysiological studies, the criterion may be a certain rate of discharge of impulses by a single cell somewhere in the nervous system The intensity of an auditory stimulus may be adjusted in order to achieve this rate of discharge for various frequencies of stimulation, or the intensity of the visual stimulus may be adjusted for each of a number of wavelengths in order to achieve this rate of discharge if the cell is one in the visual system In general,

results appear to be more nearly comparable with behavioral studies when such procedures are used in electrophysiological studies An alternative approach is to hold the energy of the stimulus constant while such dimensions as frequency or wavelength are varied and to record the neural discharge frequency as the dependent variable There is no a priori reason to assume however, that changes in the rate of response or the magnitude of response within the nervous system will bear a direct linear relation to effective magnitude of the physical stimulus The nature of the relation between stimulus magnitude and neural response is a subject of study in itself

Electrical Stimulation. In man as well as animals, direct electrical stimulation of sensory systems has sometimes been employed as a method of bypassing the primary receptor process This may provide one useful way in which limitations of the sensory responses imposed by the peripheral receptor can be revealed in man It is difficult or impossible, however, to replicate the qualitative nature of a natural or appropriate stimulus by electrical stimulation This therefore renders conclusions based on such investigations of dubious value In one area where the procedure would seem to be appropriate, the study of the temporal resolution capacity of the visual system, results with rapidly repeated electrical stimuli could be perceived as varying in time at higher rates than the maximum rate perceived as "flickering" when photic stimulation was employed In animal preparations, in addition to its value as a method of bypassing the primary receptor, electrical stimulation has also been used in an effort to determine the significance of certain efferent pathways associated with various sensory systems The role of efferent pathways is undoubtedly of great importance, but it is not clearly understood in any of the sensory systems where efferent pathways have been demonstrated anatomically

Surgical Intervention. One test of the significance of certain components in the visual system which can readily be applied with animals but never with men, at least on an experimental basis, depends upon the removal or destruction of the component. Various regions of the brain may be ablated or destroyed Nerve tracts may be sectioned Animals trained to respond to stimulation in a given way prior to such procedures may then be tested to see whether they have retained their prior ability If they have not, the conclusion that the component in question or the pathway in question is essential to the kind of discrimination under study may be justified It is always important, however, to carry out retraining procedures Sometimes surgical intervention may disrupt behavior only temporarily The demonstration of relearning ability of a given sensory discrimination may reflect such temporary disruption, or it may reveal the presence of alternative mechanisms which can be called into play following damage or destruction to the primary mechanisms which subserve the response in a normal animal Such experiments are extremely important for our understanding of sensory processes, but they are extremely difficult to interpret and must be carried out with great care and with careful attention to experimental controls

One surgical procedure that provides a measure of control within a single organism is the split-brain technique pioneered by Roger Sperry (Sperry, 1961) The optic chiasm, the corpus callosum, and other cerebral commissures are sectioned medially Communication between the right half of the brain and the left half of the brain is thereby presumably eliminated When a visual sensory discrimination is then studied by stimulation of the eye on one side this discrimination will be mediated by the visual nervous system on that same side The effects of surgical intervention at certain locations within the visual system on one side may be observed and compared with performance of the animal in the same kind of discrimination task when the other side is employed A lack of communication between the two halves of the system is supported by studies which show no transfer of discriminations learned on one side in subsequent testing of the other side The situation however, is not as clear-cut as one might hope Studies that have failed to demonstrate any transfer have been based on the use of food as a reward for correct performance Other studies have proven that when punishment is used to induce performance, there may be transfer, even when positive food rewards have failed to elicit any evidence of transfer (Sechzer, 1964) As is true especially with any form of surgical intervention, care must be exercised in the interpretation of results of experiments with the split-brain preparation

Although it is not possible to create a split-brain experimentally in man, sometimes the same effect is achieved as a result of accident or a tumorous growth which must be removed surgically Although the number of human "split-brain" subjects is limited and the precise nature of the split cannot be determined in most cases until long after experiments are performed, observations of such individuals have provided useful information concerning the laterality of the cortex in the processing of certain sensory information and the mediation of certain kinds of behavior This is particularly helpful in the studies of language (Gazzaniga, 1967)

Computer Analysis. In recent years, investigators of sensory processes have become increasingly concerned with the detailed nature of temporal patterns of neural response Whereas such patterns can be studied only with the greatest difficulty from kymograph records, they can be subjected to elaborate analyses with the aid of digital computers To date, the results of complex computer analyses have not been of far-reaching importance, but it seems likely that ultimately computers will play a highly significant role in the understanding of sensory processes in particular and the functioning of the entire central nervous system in general

NEURAL RESPONSE TO STIMULATION

Graded Potential The nature of the initial response of a receptor system to stimulation varies with the sensory modality In most instances, the initially detectible electrical response is in the form of a graded potential That is, the amplitude of the response varies, or is graded, dependent upon the amplitude of stimulation Such a response may be relatively sustained during the time course of stimulation, although frequently it will show an initial maximum level which may reduce somewhat with continuation of a sustained stimulus The origin of such graded potentials is not clearly understood, although they may arise in primary receptors They differ from the spike discharge of neurons in that their amplitude may vary, and that they are sustained in duration rather than occurring repetitively with sustained stimulation Polarity of the graded potential may vary dependent upon the nature of the stimulus (Fig 8 1). Records obtained in the region of the retinal receptors show a difference in the polarity of the response dependent upon the wavelength of the stimulus (Mac Nichol and Svaetichin, 1958) Only in the case of the olfactory system does the primary receptor serve also as the primary neuron, discharging with impulses, the frequency of which varies with the concentration of the stimulating substance

In the visual system, as detailed in a subsequent chapter, there is evidence that initial responses at the receptor and cells associated directly with the receptor may be a hyperpolarization Hyperpolarization in one cell apparently can give rise to depolarization of a cell with which it makes contact and subsequent neural discharge of that cell which is propagated along an axon

The Generator Potential. Before a cell will fire there must be a depolarization of the cell membrane to a certain "threshold" level When this level is reached, the spike discharge follows In the wake of a spike discharge, the sustained stimulation of the cell by contacting elements results in a repetition of the process If the depolarization does not reach the re-

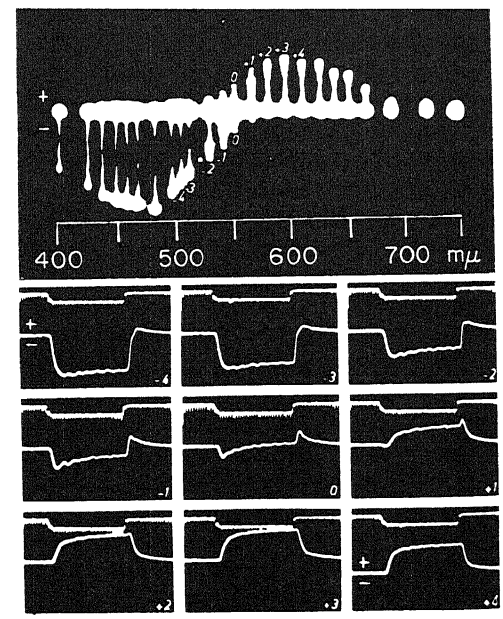

Fig 8 1 Microelectrode records of S (slow) - potentials in the retina of the fish The upper portion of the figure indicates the relative polarity of response as a function of the wavelength of the stimulus Lower records show the time course amplitude and polarity of responses to 300 msec stimulation The stimulus is marked by a slight downward deflection of the timing trace (MacNichol and Svaetichin 1958)

quired level, the cell will not discharge (Fig 8 2) It is evident that as level of stimulation is increased, the generator potential reaches the critical amplitude more rapidly, permitting a more rapid frequency of discharge of the cell The spike discharge occurs on top of the measurable generator potential The generator potential is monophasic, of relatively short latency and, as suggested above, may be graded in amplitude It thus is distinguished from the propagated action potential which is of roughly constant amplitude for a given nerve fiber

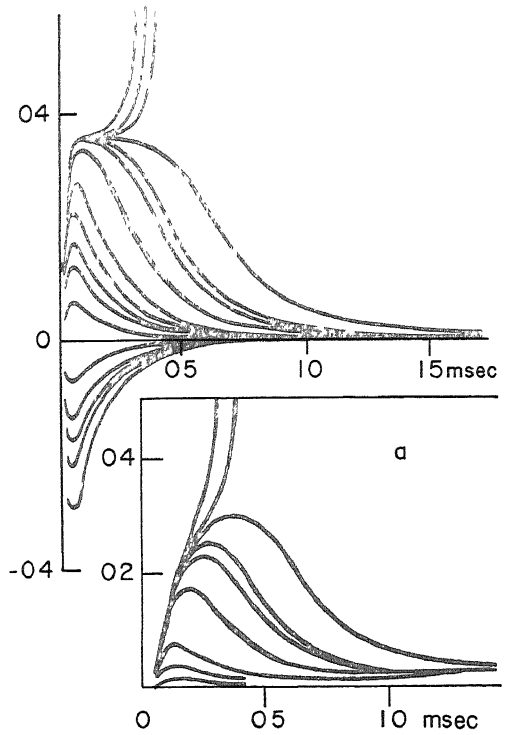

Fig 8 2 Generator potential resulting from cathodal shock to large diameter crab nerve fiber Successively higher amplitude curves result from increase in shock strength At a shock strength of slightly less than 15 mv the amount of membrane depolarization requisite to spike discharge is reached and the cell fires (After Hodgkin 1938)

Nerve Fiber Discharge. The pattern of a nerve fiber's discharge frequency may vary considerably depending upon the nature of stimulation as well as the specific modality under consideration With the initiation of a stimulus, spike discharge frequency may be very rapid after a short latency, followed by a sustained discharge frequency at a higher rate than the resting level until the stimulus is terminated Upon termination of the stimulus, there may be a brief period of inhibition of any response prior to resumption of some resting level of response Some fibers may be quiescent and show no detectible resting level of discharge The relation of discharge frequency to intensity of stimulation is illustrated in Figure 8 3 for a single optic nerve fiber of the horseshoe crab It is evident that as the stimulus intensity is reduced, latency of response grows longer, the initial frequency of discharge is lower, and the repetitive discharge of the unit, while the stimulus remains on, becomes slower and less regular

By reason of interaction processes within sensory systems, not all cells respond with heightened discharge activity upon stimulation Some may be inhibited by a stimulus (Fig 8 4) The top trace shows a unit which

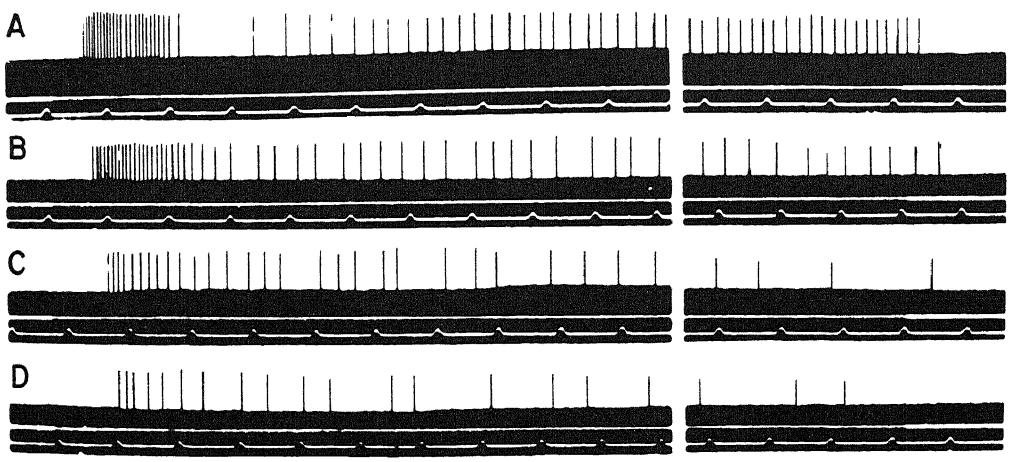

Fig 8 3 Discharge of a single optic nerve fiber of *Limulus* for stimulation at each of four levels of stimulus illumination A 6 3 × 10^4 B 6 3 × 10^3 C 6 3 × 10^2 and D 6 3 × 10 meter candles (Hartline and Graham, 1932)

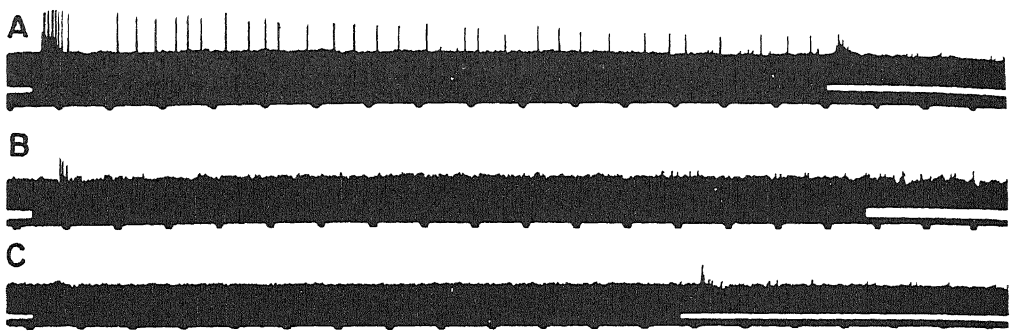

Fig 8 4 Three different types of discharge from retinal fibers of the frog Stimulus duration is shown by the darkened portion of the white line above the fifth-second time marker (Hartline 1938)

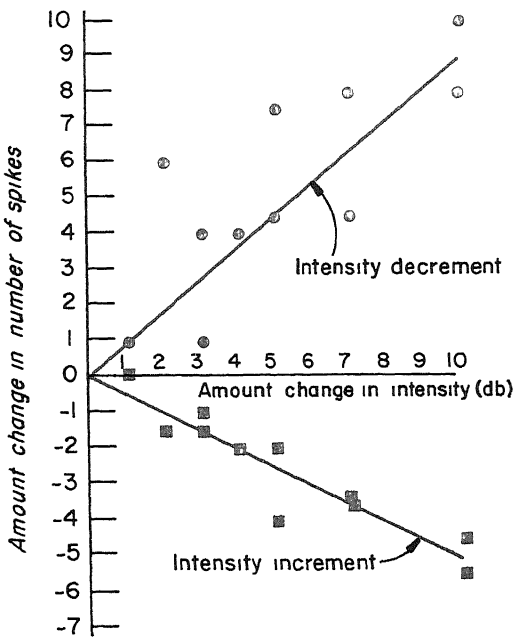

Fig 8 5 Changes in number of spike discharges associated with brief changes in stimulus intensity for a monkey lateral geniculate cell (DaValois Jacobs and Jones 1962)

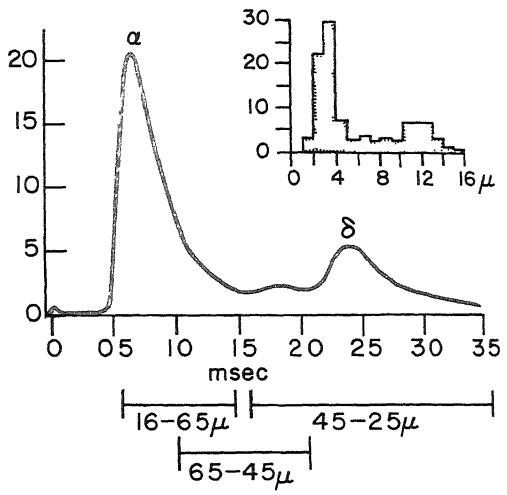

Fig 8 6 Compound potential in a human sensory nerve voltage (arbitrary units) as a function of time Ranges of fiber diameters are shown below the time axis (Gasser 1960)

responds initially with a rapid burst of activity and then a sustained level of activity while the stimulus remains on The middle trace illustrates a unit which responds with a burst of activity upon initiation of the stimulus, relative quiescence while the stimulus is maintained, and absence of activity upon termination of the stimulus The bottom trace shows a unit which responds not at all but rather is inhibited when a stimulus is presented Upon termination of the stimulus, a burst of activity occurs and is sustained for some time prior to return of the unit to its resting level

In the visual system, certain ganglion cells may respond with increased activity upon illumination of a certain region of the retina and decreased activity as illumination is reduced There are also cells which respond directly opposite to this Activity increases with a decrement in intensity of the stimulus and decreases with an increment in the stimulus The activity of this kind of a unit as a function of the amount of change of the level of stimulus intensity in decibels (ratio steps of 1 26) is illustrated in Figure 8 5 Obviously, for any cell to show a decrement of response to some form of stimulation, as compared with the absence of any stimulation, there must be a resting level of activity which can be decreased

Neural Coding of Stimulus Information. It is evident that information is encoded in neural activity in terms of the rate of that activity Changes in stimulus intensity are reflected by increase or decrease in spike discharge frequency Complex patterns of temporal change of stimulation are probably also reflected in terms of the temporal pattern of spike discharge The possibility of a temporal encoding in the spike discharge of other than temporal aspects of the stimulus dimension has been considered but cannot be supported by substantial experimental evidence The most important aspect of coding of information transmitted by neurons seems to be that of the identity of the neuron The nature of the messages in terms of their spike discharge frequency is remarkably similar from one sensory modality to another Apparently, the specific neurons which carry the message, by reason of their identity, their origin and their termination, relate to specific qualitative aspects of the stimulus as these are interpreted by the brain

Compound Action Potential. When a bundle of nerve fibers is transmitting information in response to sensory stimulation, a compound action potential may be recorded from the bundle with a gross electrode This shows changes in voltage with time which reflect the summed electrical activity of all of the components within the bundle When a large number of fibers is firing simultaneously or at nearly the same time, the amplitude of the action potential will be high Compound action potentials typically show several peaks, associated with classes of neurons having roughly comparable conduction velocities Thus, a wave of activity for a given class of fibers reaches the electrode at very nearly the same time for all of the fibers within the class These fibers are then represented by a specific component of the compound response (Fig 8 6)

The Physics of Sound and the Biophysics of Hearing

Hearing rivals vision as a means of deriving highly complex and detailed information from the environment In humans, endowed with speech, it is the most important channel for interpersonal communication Hearing is the detection of vibrations transmitted through an elastic medium It has evolved from vibration-sensing organs, examples of which may be found in many species more primitive than man and the higher animals The term "sound" is usually reserved for those frequencies of vibration to which our hearing apparatus will respond, but if we generalize even over the mammalian species, this covers a range of frequencies much broader than those that can be detected by man Differences lie in the structure of the detecting apparatus, its size and physical characteristics In the higher animals, the differences in most instances may be dismissed as quantitative rather than qualitative, and much of our knowledge of the physiology of hearing is derived from infrahuman species such as the cat and the guinea pig

THE PHYSICS OF SOUND

The physical stimulus for hearing is a longitudinal pressure wave consisting of periodic compression and rarefaction, which requires an elastic medium for its transmission The frequency of sound is determined by the originating source and remains invariant as the sound is transmitted through various media Velocity and wavelength are related by the expression $V = f \times \lambda$, where V represents velocity, f is frequency, and λ stands for wavelength

The velocity of sound in air is approximately 330 meters/sec, while in water it is nearly 1500 meters/sec The way in which the propagation of sound is impeded in a given material varies with frequency Impedance refers to the attentuation of amplitudes and not to velocity One component of impedance increases with the elasticity of the material, but varies inversely with the frequency of the sound On the other hand, the higher the mass of a given material, the higher its contribution to impedance This contribution increases directly with frequency These two reactive components of impedance, that contributed by the elasticity (s) and that by the inertial mass (m)—characteristics of the material—are of opposite sign and add algebraically The third component of impedance is the resistive component, this is added vectorially to the algebraic sum of the reactive components It is independent of frequency The complete expression for mechanical impedance, Z, is

$$Z = \sqrt{[2\pi fm - (s/2\pi f)]^2 + R_m^2} \qquad (1)$$

where R_m is the frictional resistance in ohms The total impedance is a minimum when the reactive component $2\pi fm - (s/2\pi f)$ is a minimum This will be the case at that frequency where these components are equal in absolute value and hence will cancel each other out Thus, by setting $2\pi fm$ equal to $s/2\pi f$ one can solve for frequency where the reactive component is 0 The resulting equation is

$$f = \frac{\sqrt{s/m}}{2\pi} \qquad (2)$$

This provides a method of calculating the natural frequency of a given material, that frequency for which the attenuation of the material is minimal

Sound may be transmitted from one medium to another, but the efficiency with which this occurs will vary depending upon physical characteristics of the media The more nearly their impedances are the same, the greater will be the efficiency of transmission It is important to have some knowledge of the effects of impedance and how this changes with materials and with frequency to understand the auditory mechanism

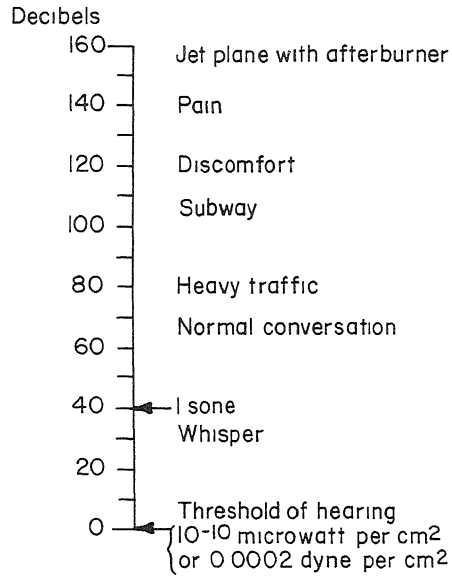
Sound is vibration, and vibration may be described in terms of its frequency and ampli-

tude The most interesting and important sounds, however, are not simple vibrations Speech and music, for example, are exceedingly complex, and the information conveyed by such sounds is in no way uniquely dependent upon specific frequencies or even frequency complexes Rather, it is the nature of relations among the frequency components of the complex sound and the way these are distributed in time which render music recognizable and enjoyable, or speech intelligible

The fact that complex sounds can be considered to consist of sinusoidal components provides some justification for the use of simple sinusoidal stimuli in the study of the auditory mechanism The ability of the ear to discriminate one sinusoidal frequency from another may be of relatively small importance for normal communication, but it is this basic capability which permits the recognition of complex sounds from which important information may be extracted Single sinusoidal frequencies of pure tones and brief clicks have been the most frequently used stimuli in the study of audition A brief click may be characterized as a broad band of frequencies compressed into a narrow interval of time "White" noise has also been used It is so named by reason of the fact that it consists, as does white light, of a broad band of frequencies which are of approximately uniform amplitude as well as of random phase relation

THE DIMENSIONS AND SPECIFICATION OF SOUND

The *frequency* range of sound to which the human ear responds is from 16 or 20 Hz (Hertz, or cycles/second) to 20,000 Hz There is a gradual reduction in the upper limit of this range with increasing age The range of sound *intensities* to which the ear can respond normally is extremely broad At the frequency of maximum sensitivity, between 1000 and 3000 Hz, the ratio of maximum intensity that can be heard without damage to the ear, to the minimum intensity that can be detected, is approximately 10^{12} The minimum power to which the ear can respond is of the order of 10^{-16} watt/cm ^{2} This is a standard reference value, in fact, many individuals can detect lesser amounts of power This power level is comparable to a sound pressure of approximately 0 0002 dyne/cm ^{2} at 20° C



The tremendous range of physical energy to which the ear responds as well as the nature of the response of the auditory system renders the use of a logarithmic scale desirable for the specification of sound intensity Such a scale represents increases in ratio steps The unit used in audition is the decibel A unit of 1 bel (named after Alexander Graham Bell) represents a ratio increase by a factor of 10, 2 bels a factor of 100, etc There are thus only 12 bels over the range from approximate threshold to the level at which sound becomes painful in the frequency range of maximum sensitivity The decibel (db) was devised as a unit which would provide a finer index of sound level As the name implies, there are 10 db to the bel, but this obviously does not mean that a decibel represents a ratio increase by a factor of one The meaning of the decibel is best understood by illustration of the method of computation

$$\text{No of db} = 10 \log (J/J_0) \qquad (3)$$

The logarithm to the base 10 of the ratio of a given power level, J, to some reference level, J_0, provides a statement as to the number of bels J is above or below the reference level By multiplying this logarithm times 10, the answer is converted to decibels The number 10, by which the logarithm is multiplied, is also the logarithm to the base 1 26 of 10, that is, 1 26 raised to the 10th power equals 10 By multiplying a logarithm to any given base (e g , 10) by the logarithm of that base to some other number as a base, the logarithm is transformed to that for the other number as base Decibels are thus logarithms to the base 1 26 and 1 db represents a ratio of 1 26

Sound intensity is properly a specification in terms of *power* level The power J is proportional to the sound pressure times the velocity of a particle in the medium through which the sound is being propagated The latter, in turn, is directly proportional to pressure Thus, sound power is proportional to pressure squared If one sound has a pressure 10 times as great as another, they are said to differ by 20 db The ratio of the pressures is only 10, but the ratio of the powers of the two sounds is 100 and the difference between them in decibels is therefore 20

The decibel notation has been applied in comparing electric powers, voltages, and currents. It is a useful notation, but it must be remembered that it is an arbitrary one and

Graph 1 A decibel scale showing approximate intensity levels produced by various sources The sone is a unit of loudness based on ratio estimates The reference for such estimates is the loudness of a 1000-Hz tone at 40 db (Stevens 1958)

that its relation to actual physical values depends upon a knowledge of the reference level employed Standard reference levels used frequently include 0 0002 dynes/cm ^{2}, or 10^{-16} watts/cm ^{2} The former is the standard reference adopted by the American Standards Association, as mentioned above, the two levels are equivalent at 20° C They represent a level of sound near threshold for the frequency of maximum sensitivity in the normal ear A reference level of 1 dyne/cm ^{2} is also used by some investigators In addition, decibel notation may be employed to represent the amount of attenuation of a signal below the maximum level that can be obtained from a given amplifier This is appropriate in order to afford a relative scale in many experimental procedures The numerical values are quite arbitrary, however, so far as their relation to any fixed physical standard is concerned, and this must be recognized in interpreting data expressed in this fashion The levels in decibels of some typical sources of sound are shown in Graph 1 relative to the standard reference The *sone* is a unit of loudness based on a subjective ratio scaling technique

ANATOMY AND PHYSIOLOGY OF THE EAR

The human ear functions in air, and, understandably, represents a fairly efficient device for the reception of sound transmitted through air When functioning normally, it is stimulated by pressure waves transmitted through air and along the external auditory canal, or external meatus, to the eardrum, or tympanic membrane Here, the medium of transmission changes but sound continues to be transmitted in the form of mechanical vibratory energy up to the point where the mechanisms of the inner ear are stimulated At that point there is a conversion of the stimulating energy to neural activity in the receptors which permits the discrimination of sounds that differ in character As mentioned earlier, the ear responds to frequencies between approximately 20 and 20,000 Hz It is not equally responsive to all of these frequencies, however, as illustrated in Figure 8 7 Optimum response occurs at approximately 2000 Hz The nature of this frequency response is determined in large measure by the physical characteristics of the receiving organ, the nature of the external auditory canal, the tympanic membrane, the chain of small bones which link the tympanic membrane through the middle ear to the fluids of the inner ear, and finally the coupling of sound into these fluids which surround the receiving mechanism, the basilar membrane

The external ear, or pinna, serves some function in channeling energy into the ear and in influencing the directional response of the ear It is not nearly so important in man as it is in lower animals In some animals with highly

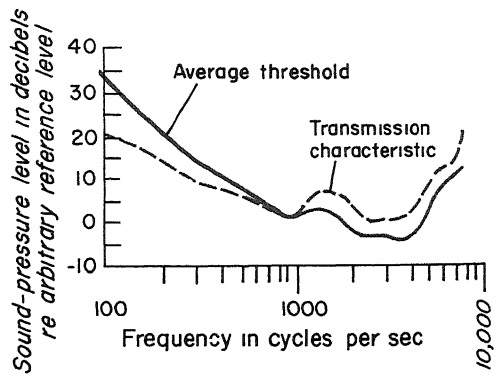


Fig 8 7 Transmission characteristic of the ear based on the summed impedances of the tympanic membrane malleus and incus the middle ear cavities and the stapes cochlea and round window membrane as calculated by Zwislocki Comparison with an average threshold curve illustrates the important influence of the physical characteristics of the auditory mechanism on the frequency response function in hearing (Zwislocki 1965)

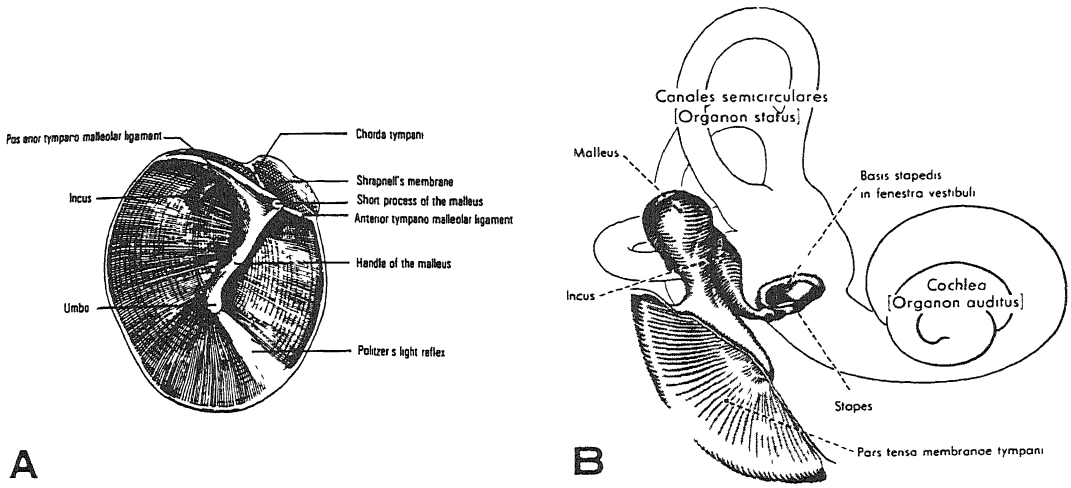

Fig 8 8 *A* Lateral surface of the right tympanic membrane as seen with the otoscope (Portmann 1951) *B* Cut away section of the tympanic membrane showing the nature of attachment of the malleus along with its linkage via the incus and stapes to the oval window of the labyrinth (Mellonı 1957)

refined motor control of the external ear, it is an important factor in the localization of the origin of sound Sound is transmitted along the external meatus to the tympanic membrane which is set in motion by the sound vibrations Its total area is approximately 70 mm ^{2} The first of the bones of the middle ear, the malleus, is attached to the inside of the tympanic membrane by its footplate The appearance of the membrane and the point of attachment of the malleus may be visualized in Figure 8 8 The malleus is connected via an intermediary linking bone, the incus, to the stapes, which in turn is attached to the oval window of the cochlear mechanism The bones of the middle ear are surrounded by air which is ordinarily at approximately the same pressure as the external atmosphere Pressure in the middle ear is equalized via the eustachian tube which extends from the middle ear to the pharynx If one calculates the lengths of the bones in the ossicular chain and considers the way in which they are articulated, the mechanical advantage from tympanic membrane to oval window appears to be approximately 1 3 This is probably of relatively little importance, however, and may serve merely to offset the frictional resistance which exists along this pathway

Up to the level of the tympanic membrane the receiving organ is a completely passive organ At this point, however, it may be influenced internally The articulation of the small bones of the middle ear can be influenced by the middle ear muscles, the tensor tympani and the stapedius Increased tension in these muscles reduces the efficiency of transmission of low sound frequency (<1000 Hz) along this pathway Contraction may therefore serve as a protective device, and in fact, it can be demonstrated that contraction of the stapedius muscle occurs as a reflex response to loud sounds As in the pupillary reflex of the eye, this response is consensual so that contraction in both ears is elicited by stimulation of only one ear This system thus provides a feedback loop for control of the auditory receptor It may afford some protection against loud sounds, but the latency of the reflex is too great for this to be of major significance A more important function may be in the reduction of the masking effects of low frequency sounds Low frequencies are particularly effective in the masking of other frequencies, but relatively unimportant with respect to information content

The footplate of the stapes connected to the oval window is approximately 3 mm ^{2} in area When this is considered in relation to the *effective* area of the tympanic membrane, approximately 40 mm ^{2}, it is evident that there is a mechanical advantage of 13 to 1 between the tympanic membrane and the oval window This provides for a reasonable impedance match between the external medium of propagation, air, and the internal medium of propagation, the perilymph of the cochlea

Sound waves are transmitted very rapidly

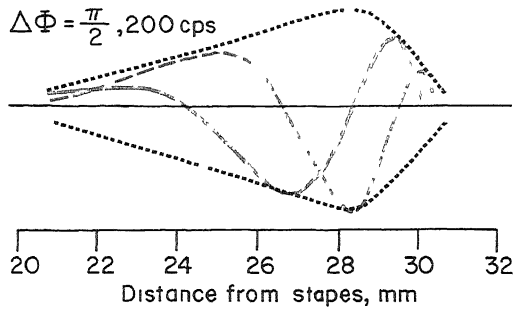

Fig 8 9 Traveling wave along the cochlear partition for a 200 Hz tone The solid line indicates the deformation pattern at a given instant The line with the short dashes shows the same traveling wave one-fourth of a period later The envelope shows the maximum displacement at each point (von Bekesy 1947)

through the perilymph of the vestibular canal around the approximately 2¾ turns of the cochlea to its tip, then through the helicotrema, the connecting point between this canal and the tympanic canal which carries the sound vibrations down to the round window As the oval window bulges inward, the round window bulges outward in compensation The basilar membrane which lies between these two canals is thus surrounded by liquid through which a sound wave is being propagated There is very little delay between the arrival of sound pressure increases at the oval window and the bulging out of the round window in compensation Nonetheless, the actual transmission of vibrations along the basilar membrane caused by the stimulating sound can be shown to be somewhat delayed with respect to the transmission of sound through the liquid medium of the inner ear The reason for this is that sound is coupled into the basilar membrane almost solely at its base The physical characteristics of the basilar membrane are such that it is relatively stiff at the base and becomes less so along its length toward the apex The change in stiffness is by a factor of 100 along the entire length At the same time, the membrane becomes broader toward its apex This is true even though the cochlea as a whole is becoming narrower Thus, the increased breadth of the basilar membrane occurs at the expense of the size of the liquid-filled canals

Observations of the basilar membrane have been made with stroboscopic illumination in order to determine the nature of its motion in response to sound stimulation It is fairly well established that the membrane is set in motion at the base and that traveling waves move out along the membrane from the base toward the tip The reason for this is the efficiency of the coupling of sound by reason of impedance matching between the perilymph and the base of the basilar membrane and the relatively broad frequency response characteristics of the base Vibrations are transmitted out along the membrane but are attenuated as they approach its tip The amount of attenuation increases with the frequency of the sound As the membrane becomes less stiff, higher frequencies of sound are damped to a greater extent

There are not fixed, individual points along the membrane which, at a given frequency of stimulation, represent maximum amplitudes of excursion or minimum amounts of excursion, i e , nodal points, rather the point of maximum amplitude progresses along the membrane out to a distance which is determined by the frequency of the stimulus The lower the frequency of the driving sound pressure wave, the greater the proportion of the membrane which is set in motion For frequencies of up to about 20 to 30 Hz the entire membrane is set in motion and it vibrates in phase That is, all along its length it is moving either up toward the vestibular canal or down toward the tympanic canal at the same time For frequencies of up to about 200 Hz , the entire membrane is set in motion but there will be at least one phase change along its length Part of it will be moving in one direction and another part in the opposite direction As suggested earlier, the wave will move along the membrane as the motion occurs For frequencies above the 200 Hz level, less than the entire membrane is set in motion and the higher the frequency, the less will be the length of the membrane which moves The envelope of the traveling wave which moves along the membrane is relatively constant for a given condition of stimulation That is to say, the maximum aplitude which any given point on the membrane will reach is a constant, although that point may sometimes be moving with its maximum amplitude and at other times may barely move at all These ideas are illustrated in Figure 8 9 The envelope of the traveling wave is shown and the nature of the excursion of the basilar membrane at any given point is illustrated by the lines drawn within the dashed lines which rep-

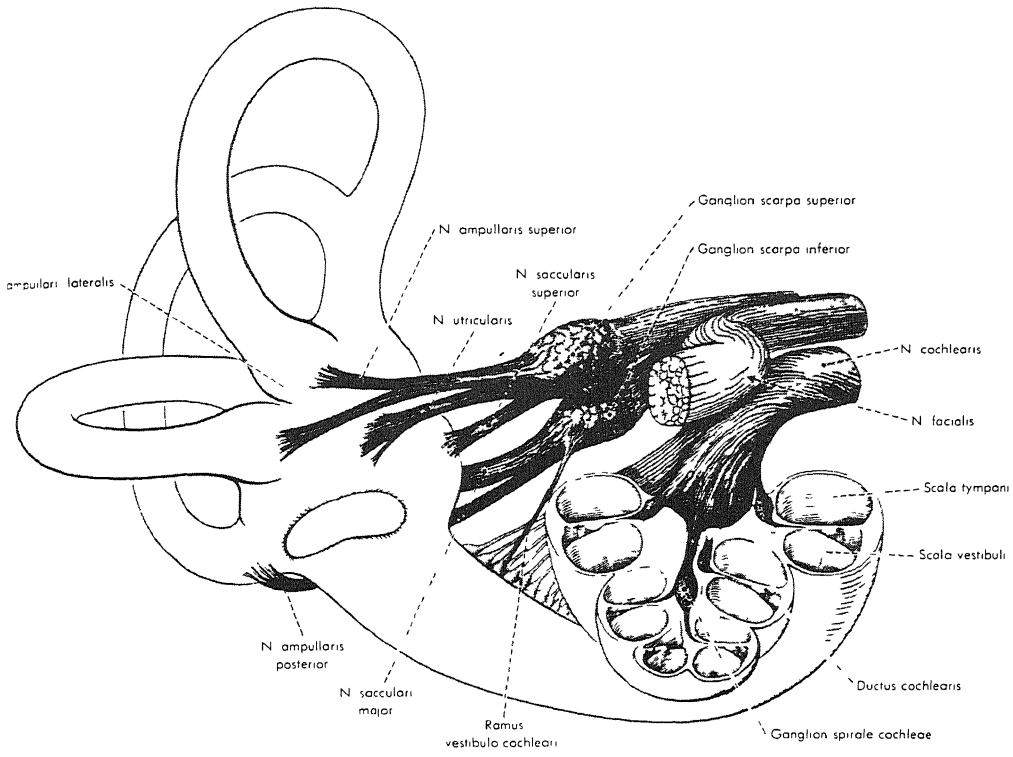

Fig 8 10 A midmodiolar section through the right cochlea shown in relation to the vestibular system with vestibular and cochlear divisions of the eighth nerve (Melloni 1957)

resent the limiting envelope The short-dashed line and the solid line represent two different points in time and two different degrees of progression of the traveling wave along the membrane It is thus clear that the nature of the motion pattern of the basilar membrane is determined by the frequency characteristics of the sound stimulation The motion characteristics are not simple, however, and even though one point along the membrane may represent a greater maximum amplitude of excursion than any other for a given single frequency of stimulation, the way in which it is moving will vary with time during the course of its stimulation

In summary, virtually all of the energy transmitted to the inner ear is absorbed by the basilar membrane at its stiff basal end, and motions of the basilar membrane are propagated along its length toward the broader, less stiff apex most efficiently for lower frequencies that are less damped by this organ The nature of the motion pattern is a characteristic of the stimulating frequency, hence, the pattern of excitation of receptors distributed along the length of the membrane is also determined by the nature of the stimulus The nature of the motion will be complex for a complex stimulus, but will be unique and characteristic of any unique stimulus complex For a given frequency of stimulation, the nature of the motion pattern will be altered by the amplitude of stimulation The greater the amplitude, the greater will be the amplitude of excursion of the basilar membrane and the greater will be the length of the membrane involved in the motion for those frequencies higher than that for which the entire length of the membrane is all ordinarily set in motion As illustrated in Figure 8 9, the envelope of the traveling wave shows how damping results in the falling off of amplitude of motion to zero beyond a certain region of the membrane at a given frequency The nature of the motion of the basilar membrane follows from its physical characteristics Actually, observations by von Békésy (1960) of the motion provided important clues to the physical characteristics of this organ

How the system permits discrimination of one frequency from another has been the sub-

ject of extensive debate, but it is clear that the pattern of motion of the basilar membrane is characteristic for a given sound It is reasonable to assume that the ability of the system to analyze sound is a result of both temporal and spatial patterns of excitation of the receptors along the length of the membrane For a certain frequency, a certain part of the membrane is driven to motion of the greatest amplitude, but it might be an oversimplification to suggest that those receptors in the region of maximum amplitude are exclusively responsible for the detection of sound of that frequency This problem is discussed further below

TRANSFORMATION OF ENERGY

One of the most interesting problems in understanding the auditory system is that of how mechanical energy of motion of the basilar membrane is converted into neural activity To pursue this question it is necessary to examine the anatomy of the cochlear system in some detail The cochlea is shown in Figure 8 10 in its relation to the rest of the labyrinthine mechanism The cross section of part of a single turn of the cochlea is illustrated in Figure 8 11 The tectorial membrane is connected to tissue which is in turn attached to

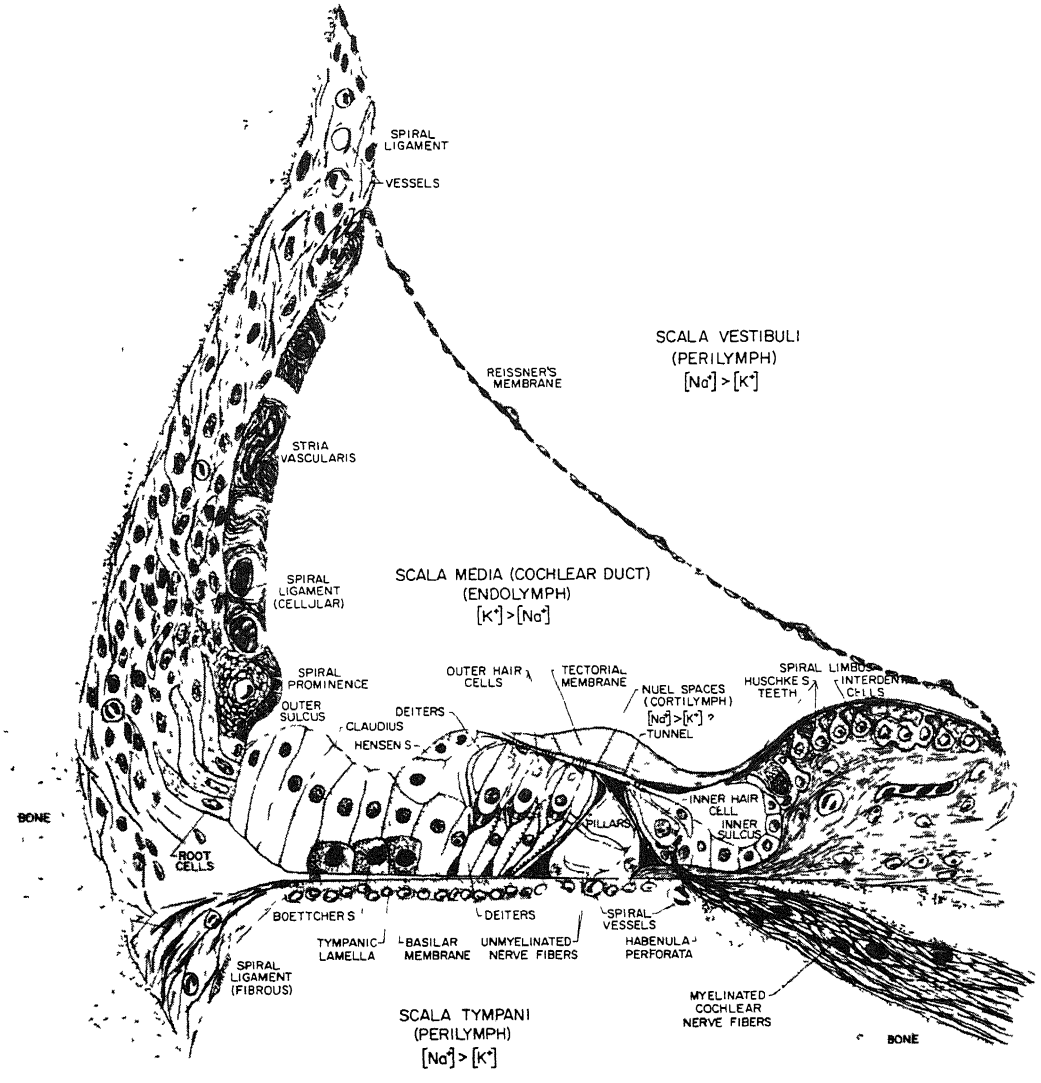

Fig 8 11 The major cochlear structures as seen in a transverse section of the cochlear duct from the upper portion of the first coil of the guinea pig

the central spiral laminar bone This membrane extends out over the hair cells which in turn arise from the cells of Deiters on the basilar membrane

The tectorial membrane is not attached to the hair cells and may move relative to them Such relative motion causes bending of the hair cells and it is the bending which initiates neural activity The hair cells are the primary sensory elements As illustrated in Figures 8 12 and 8 13, outer and inner rows of hair cells are separated by pillar cells or the rods of Corti which form a tunnel or arch The height of this formation increases from the base to the apex The single row of inner hair cells is found on the side of the cochlear spiral toward the center, the three or more rows of outer hair cells are on the outer side of the arch Just inside of the inner hair cells is located the inner sulcus and medial to this is a spiral ridge, the limbus spiralis, to which the fibers of the basilar membrane are anchored Reissner's membrane (Fig 8 11) is attached to the inner margin of the ridge and the tectorial membrane, which overlaps the hair cells, is attached to its surface The tectorial membrane is in contact with the hair cells but they do not penetrate its surface The hair cells are bathed in fluid but it cannot be the endolymph of the medial canal because the potassium content of

the endolymph is so high that it would be impossible for the unmyelinated fibers which innervate the hair cells to fire in such a medium The cells of Hensen lateral to the outer row of hair cells may serve as a block to prevent the mixing of the fluid around the hair cells with endolymph The nature of this fluid must be more like that of perilymph than endolymph, but its analysis is presently unknown The various constituents of perilymph and endolymph and their approximate concentrations are given in Table 8 1

After Smith, Lowry, and Wu

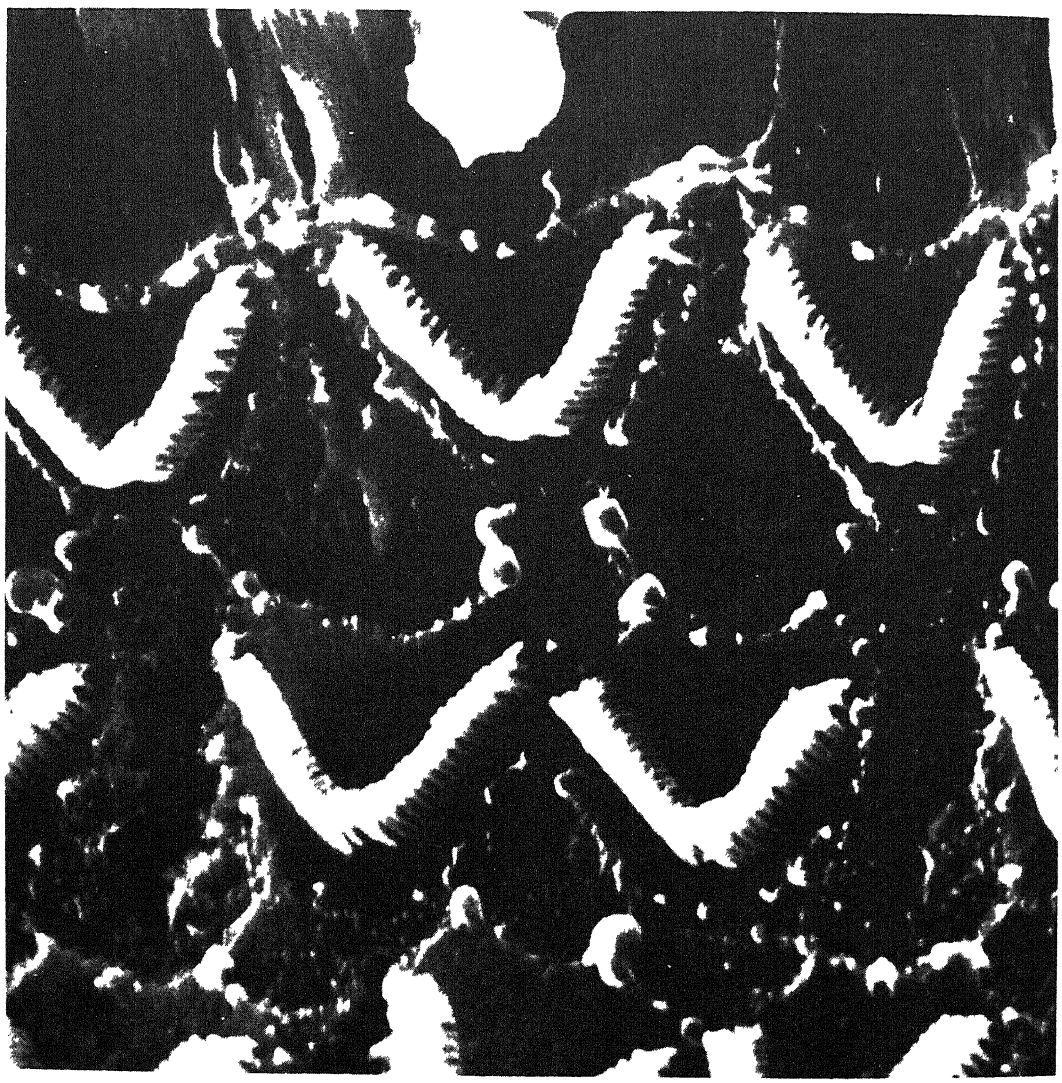

Fig 8 14 Scanning electronmicrograph of outer hair cells in man showing characteristic formation of the hairs (Photograph provided through the courtesy of Hans Engström)

It has been estimated that in man there are from 12,000 to 20,000 outer hair cells and 3500 inner hair cells in each ear (Retzius 1884, Guild, 1932, Chow, 1951) Their relative shapes are illustrated in Figure 8 13 There are as many as 120 to 140 hairs (stereocilia) on the ends of each outer cell, arranged in several rows in a W-shaped pattern (Fig 8 14) At the base of the W is a single basal body or centriole The inner hair cells differ significantly in shape, have fewer hairs (50 to 60) and also have a single basal body or centriole (Ades, Engstrom, and Hawkins, 1962) The interior structures of these cells are shown in Figure 8 13

The way in which the energy of motion of the basilar membrane is transmitted to the hair cells and they in turn transform it into neural activity is not entirely clear The basilar membrane is attached on both sides of the cochlear canal The tectorial membrane is attached only on the side adjacent to the modiolus, the center of the spiral Motion of the membrane apparently causes a rocking motion of the rods of Corti and the hair cells, and this in turn results in a shearing motion between the ends of the hair cells and the tectorial membrane Thus, as the basilar membrane moves up and down, the tectorial membrane slips relative to the tops of the hair cells and tends to bend them The precise nature of this shearing motion undoubtedly differs in different regions of the system, depending on the nature of the stimulus and its relative intensity Out near the end of the envelope of the traveling wave, the hair cells are apparently bent in a longitudinal direction along the long axis of the basilar membrane Cells located closer to the base may tend to be pressed down while other hair cells still closer to the base appear to be bent laterally (von Békésy, 1943) The probable extent of the lateral shear and the longitudinal shear relative to the envelope of a traveling wave based on calculations by Tonndorf (1960) are illustrated in Figure 8 15

The hair cells of the inner ear are analogous to other cells found in the utricular mechanism and in the lateral line organs of some species These other cells are more readily accessible and hence more easily studied They possess a kinocilium, a kind of stereobody with a projecting cilium It has been demonstrated that bending of the individual hairs, or cilia, in the

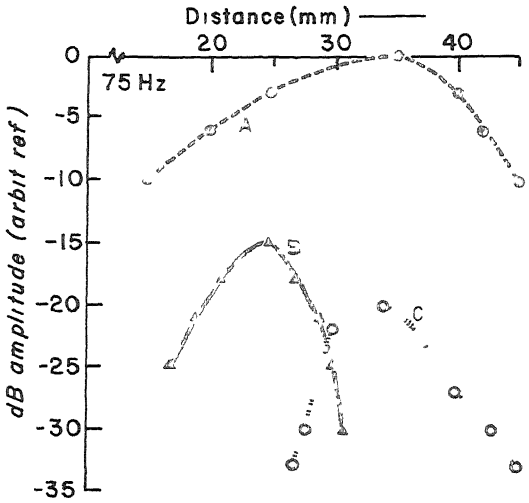

Fig 8 15 Envelopes of the three modes of motion in a cochlear model (*A*) traveling wave (*B*) radial shear (*C*) longitudinal shear The maximum amplitude of the traveling wave pattern is arbitrarily set at unity The ordinate is given in decibels of attenuation Note that the transformation of the traveling wave motion into shear motion is accompanied by an amplitude reduction by a factor of 15 to 20 db (Tonndorf 1960)

direction of the kinocilium in these other cells results in cell depolarization (Lowenstein & Wersäll, 1959) Bending in the opposite direction results in hyperpolarization By analogy, one might assume that bending of the hairs of the cells of the inner ear laterally and away from the cochlear center would cause depolarization, for it is in this direction that the basal bodies or centrioles are located The problem has not been resolved, however Von Békésy (1953) has studied the matter and reports that the inner hair cells appear to be bent longitudinally while the outer hair cells are bent laterally As mentioned above, the basal body is oriented laterally and away from the center for both outer and inner hair cells. Engstrom et al (1962) have argued that the structure of the inner hair cells is such that they should be expected to respond to lateral shear while outer hair cells might be expected to respond to bending in a variety of directions Thus, the precise nature of the mechanism of action which gives rise to the excitation of these cells is not known The hairs, themselves, must transmit the mechanical motion to the interiors of the cells The problem in interpretation of how the hair cells work rests in part with their incredible sensitivity At threshold,

based on measurements of movement of the malleus (Wilska, 1935) and stapes (von Békésy, 1960), movements of the basilar membrane must not be very much greater than 10^{-9} centimeters This is less than the thickness of the plasma membrane of the hair cells themselves

It is difficult to discern what kind of mechanism permits the conversion of such minute mechanical displacement into a significant amount of neural activity One point is clear, the process is an active one The energy of the activity elicited by stimulation greatly exceeds the energy of the stimulus at threshold The receptor itself, dependent upon its active metabolic processes, contributes significantly to the response This has been demonstrated elegantly by experiments performed by von Békésy (1960)

Neurophysiology of Hearing

THE COCHLEAR MICROPHONIC

Whatever the nature of the method of transformation of energy may be in the ear, the ultimate result must be the instigation of neural activity in the nerve fibers of the auditory system These may be expected to be accompanied by electrical activity One of the first reports of electrical activity in the auditory mechanism was that of Wever and Bray (1930) Recording from the round window of the cat by means of a gross electrode, they identified an electrical response which followed the temporal characteristics of the driving auditory stimulus with remarkable accuracy It was at first thought that this was the electrical concomitant of neural activity. Subsequent findings to the effect that this activity had virtually zero latency, was relatively less susceptible to the effects of reduced oxygen than neural tissue, and the fact that it "followed" temporal rates of change quite in excess of those which nerve fibers may be expected to follow, all suggest that this *cochlear microphonic* is more probably a by-product of the stimulation of the auditory mechanism, or an *epiphenomenon* associated with the transformation of the mechanical energy of the driving signal into neural activity

Actually, physical disturbance or vibration of organic tissue may lead to voltage changes in a wide variety of circumstances This is true of many of the tissues within the ear The primary source of the cochlear microphonic reported by Wever and Bray, however, the "first order cochlear microphonic" as von Békesy terms it, probably arises in the hair cells A variety of experiments have been performed which demonstrate that the polarity of the cochlear microphonic potential, or its phase, is reversed as a small electrode from which it is recorded passes through the region of the organ of Corti associated with the interface between the hair cells and the tectorial membrane (von Békesy, 1960, Konishi and Yasuno, 1963)

As the amplitude of a driving signal is increased, the amplitude of the cochlear microphonic also increases and it continues to follow the form of the driving signal quite accurately With still further increase in driving amplitude the amplitude of the cochlear microphonic begins to level out and may even reduce Even so, the wave form is not distorted This is a very unusual characteristic for any simple physical system It suggests that the cochlear microphonic as recorded is certainly not reflective of the activity of single units within the system, i e , single hair cells, but rather represents the summated activity of many units Fidelity of following of the wave form of the driving signal, even when amplitude begins to saturate, may reflect a low pass filtering characteristic of the overall system which serves to filter out nonlinearities imposed by the system (Whitfield, 1967)

A number of experiments have demonstrated that it is possible to record cochlear microphonics representative of a much narrower extent of the basilar membrane than the original signals recorded by Wever and Bray This is accomplished by locating electrodes on either side of the organ of Corti, one in the scala vestibuli and one in the scala tympani Recording with a differential amplifier, it is possible to exclude other signals and detect the cochlear microphonic representing as little as 1 or 2 mm of the length of the basilar membrane and its associated tissue (Tasaki, et al., 1952, Tasaki and Fernandez, 1952) The cochlear microphonic has proven a useful indicator for the determination of what portions of the basilar membrane are responding to what frequencies of the driving stimulus (Davis et al , 1953) The voltage of the cochlear microphonic in the first turn follows the velocity of the movement of the stapes and not its absolute position It thus represents the first derivative of the driving force and this serves to

explain the fact that there is an initial 90° phase lag of the cochlear microphonic with respect to the driving signal (Teas, 1970)

The mechanism of action of the hair cell remains a mystery Recently, Harris et al (1970) have demonstrated that the hair cells of the lateral line organ of the mud puppy respond with a graded potential to deflection of their cilia It has been suggested that the hair cells may be important by reason of the fact that they provide additional effective cell surface across which an electrostatic potential may appear, and that it is the movement of large charged molecules which gives rise to microphonic potentials (Dohlman, 1960)

TEMPORARY THRESHOLD SHIFT

It is not surprising that with prolonged exposure of the ear to a relatively loud sound of a given frequency there is an elevation of the auditory threshold for some minutes following exposure It is curious, however, that this temporary threshold shift (TTS) is greater for frequencies higher than that of the initial exposure by ½ to 1 octave The frequencies affected to a greater extent cause motion of the basilar membrane which is confined to a region closer to the base of the membrane Whatever the process, one might suppose that it would be greatest in the region of maximum amplitude of motion of the membrane as caused by the "fatiguing" frequency The leading edge of the envelope of the traveling wave of the frequency most affected corresponds more nearly with the point of maximum amplitude of the envelope of the traveling wave for the "fatiguing" frequency This suggests the possibility, if the effect is greatest at the point of maximum amplitude, that the portion of the membrane which is most significant for the detection of a given frequency of stimulation lies somewhere apical to the point of maximum amplitude This would be in a region in which von Békésy has suggested that the direction of shear of the hair cells is longitudinal It is difficult to resolve with von Bekésy's contention (1960) that the greatest cochlear microphonic arises basal to the point of maximum movement for a given frequency of stimulation There has been one experiment reported which would appear to provide an electrophysiological analog for the TTS frequency shift Stevens, Davis, and Lurie (1935) reported that damage to an isolated region of the cochlea of the guinea pig suppressed cochlear microphonics for frequencies higher than that which gave rise to maximum amplitude of motion of the basilar membrane in the region of the damage Subsequent studies of the correspondence between motion of the membrane and damage tend to show that damage does in fact occur in the region of maximum amplitude of motion (Davis et al , 1953)

HAIR CELL FUNCTIONS

Possible divisions of the functions of the outer and inner hair cells have long been a matter of interest It has been suggested that the inner hair cells, smaller in number, may be analogous with the cones of the retina and responsible for fine discriminations at higher sound pressure levels, while the outer hair cells are more involved in the detection of near threshold events It is recognized that there may be differences in the nature of neural connections to inner and outer hair cells Outer hair cells have been reported more often to be connected to fibers which enter the organ of Corti and then travel longitudinally along it before termination Inner hair cells are said to be connected with fibers that emerge from the nerve bundle and terminate directly on hair cells without traveling along the cochlear mechanism Suggestions that connections from inner hair cells may be more direct and that many outer hair cells may be connected to a single pathway have not been substantiated by recent electronmicroscopy (Whitfield, 1967)

Inner hair cells seem to be better protected from physical damage than outer hair cells (von Békésy, 1960) but would appear to be more sensitive to reduced oxygen levels than are the outer hair cells If indeed the inner hair cells prove to be activated by longitudinal bending near the apical front of the traveling wave envelope and are primarily responsible for frequency discrimination, while the outer hair cells are activated primarily by lateral bending in the region of maximum amplitude of excursion of the membrane and basal to this point, then the frequency shift which accompanies a temporary threshold shift could readily be explained There are too many conflicting items of evidence for this to be accepted as a firm conclusion at this juncture, however

It has been estimated that when the ear is stimulated by a 40-db tone at 1000 cycles, approximately 3000 hair cells may be activated With a change in frequency by a just discriminable amount, it is probable that less than 2%

of these hair cells are no longer activated and have been supplanted by others which were formerly inactive A great deal of evidence suggests that it is the overall pattern of stimulation of many receptors rather than the activity of just a few which is involved in even the relatively simple discriminations of pure frequencies from one another

ELECTRICAL POTENTIALS

Following discovery of the cochlear microphonic and the recognition that it could not represent an index of neural activity, the search for other electrical evidences of neural action continued

Summation Potential. Among other electrical indicators that have been identified is the summation potential The cochlear microphonic potential is accompanied by a shift in the direct current (DC) level of the base line There is an increase of voltage in the scala tympani with respect to the scala media This may be reversed by an increase of pressure in the scala tympani Whitfield (1967) has pointed out that the summating potential cannot be a DC component introduced by the nonlinearity of the response of the cochlear microphonic, because the amplitude of the summation potential may differ along the basilar membrane A peculiarity of the summation potential is the fact that its amplitude may increase with a decrease in temperature This is the opposite of what would be expected if it were of chemical origin Whitfield has concluded that it is a mechanical effect which may be attributed to asymmetry of the basilar membrane It has been shown that, just as is so for the cochlear microphonic, the polarity of the summation potential changes when the recording electrode penetrates the reticular lamina or region of the interface between hair cells and the tectorial membrane Its source is thus localized in the region of the hair cells (Konishi and Yasuno, 1963)

A recent study (Dallos, Schoeny, and Cheatham, 1970) has shown that the summating potential, measured between the scala tympanie and the scala vestibuli, varies in form along the cochlea with the frequency and the intensity of stimulation Of particular interest is the fact that the average of the potentials in each of these canals apparently does not reflect just remote activity with a cancellation of the local cochlear microphonic potential A negative constituent probably represents remote activity, but the positive constituent of the average is dominant in the region of maximum excitation and may represent a hyperpolarization effect in a segment of the cochlea associated with the mechanism of receptor excitation It is also of interest in relation to our discussion of temporary threshold shift above, that the peak of the summation potential, whether it is based on the difference between the scala tympani and the scala vestibuli or the average potential for those two regions, corresponds with the distal end of the traveling wave envelope rather than the point of maximum mechanical vibration of the cochlea for a particular frequency of stimulation

Regional Potentials. Relatively steady potentials may be recorded in various regions of the cochlear mechanism When referred to the perilymph, the voltage recorded anywhere within the organ of Corti is approximately −20 to −80 mv The endolymph of the medial canal, on the other hand, is at a voltage of +80 mv There is thus a voltage difference between the endolymph of the medial canal and the organ of Corti of the order of 140 mv The high voltage of the endolymph is somewhat unusual The voltage of the endolymph in the vestibular end organs is only 1 to 5 mv The endolymph of the scala media is highest in the region of the stria vascularis and has been attributed to metabolic activity of that tissue This voltage has been shown to depend upon an adequate oxygen supply and has also been demonstrated to fluctuate with motion of the basilar membrane This endocochlear or endolymphatic potential increases with downward motion as the stapes presses the oval window in and decreases with upward motion of the membrane as the oval window is drawn out (von Békésy, 1952, Tasaki, Davis, and Eldridge, 1954) The endocochlear potential is not analogous to a typical cell membrane potential because it is uninfluenced by changes in the potassium concentration of the scala tympani It would be difficult to explain in these terms in any case when one compares it to the relatively low voltage of the virtually identical endolymph in the labyrinthine mechanism It can be demonstrated fairly simply that the endolymph with its high potassium concentration has no access to the receptors within the organ of Corti If the potassium concentration in the scala tympani is increased by a small

amount, the cochlear microphonic is rapidly attenuated This suggests that the basilar membrane is permeable to potassium, but that the boundary separating the organ of Corti from the endolymphatic space is not A positive potential is always found in the region of the stria vascularis even when the endolymph is removed Thus, the high potential in this region is attributed to activity within the stria vascularis rather than to chemical action directly involving the endolymph

The Neural Action Potential With all of the electrical activity in the ear, it has been difficult with gross electrodes to isolate the action potential of the nerve fibers themselves One method of accomplishing this has been to add signals from two electrodes, one on each side of the organ of Corti The purpose is to cancel out the cochlear microphonic and reveal the whole nerve action potential Another procedure has been to use a relatively short stimulus such as a click With this procedure, in a recording from the round window the cochlear microphonic can be seen immediately, while the action potential is observed after a short latency (Fig 8 16) The latency of the action potential is correlated with frequency and the region of maximum activity along the cochlear partition, the higher the frequency the shorter the latency One interesting application of measurements of the action potential is its use as an index of the possible effect of efferent signals to the cochlear mechanism in the suppression of response to auditory stimuli

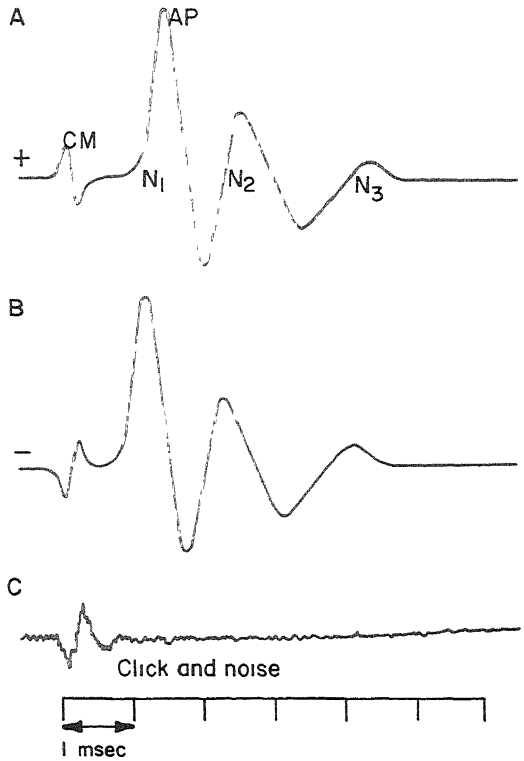

Fig 8 16 The electrical responses to clicks as recorded from the round window of the cochlea of the cat CM cochlear microphonic potential AP action potential of the auditory nerve The three components of the action potential are represented by N_1 N_2 and N_3 A reversal of polarity of the stimulus between A at the top of the figure and B results in an inversion of the cochlear microphonic but no change in the action potential except for a slight shift in latency At C the action potential is completely masked by white noise while the cochlear microphonic remains unchanged

INNERVATION OF THE COCHLEAR MECHANISM

It is estimated that approximately 30,000 auditory nerve fibers and ganglion cells (Rasmussen, 1940) subserve the total of approximately 25,000 hair cells in man (Guild, 1932) The auditory nerve contains both afferent and efferent fibers which terminate on the hair cells All of these reach the peripheral mechanism via the auditory nerve, through the core of the modiolus, through tiny holes, the habenula perforata, and then over the basilar membrane where they are unmyelinated. The work of Fernandez (1951) permits the division of these fibers into several types Radial fibers extend out from the modiolus and terminate primarily on inner hair cells Some of them penetrate the tunnel of Corti to terminate on external hair cells Longitudinal fibers extend out radially and then turn to travel as much as ⅓ to ½ turn along the cochlea in the basal direction These terminate primarily on outer hair cells but may also terminate on inner hair cells The radial fibers are attached to a relatively small number of adjacent cells in the case of both outer and inner hair cells The longitudinal fibers on the other hand, connect with many outer hair cells and may project terminations to cells in different rows along their course Just as the fibers diverge and terminate on many cells, so do processes from different fibers converge on single cells (Figs 8 17 and 8 18) The nerve endings which cluster about the hair cells may be divided into two different types the smaller ones are 0 5 to 1 0 μ in diameter with few vesicles,

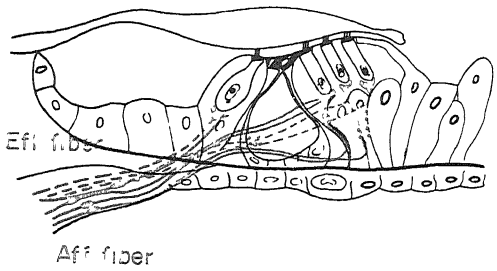

Fig 8 17 The projections of afferent (Aff) and efferent (Eff) fibers onto outer and inner hair cells of the organ of Corti (Wersall Flock and Lundquist 1965)

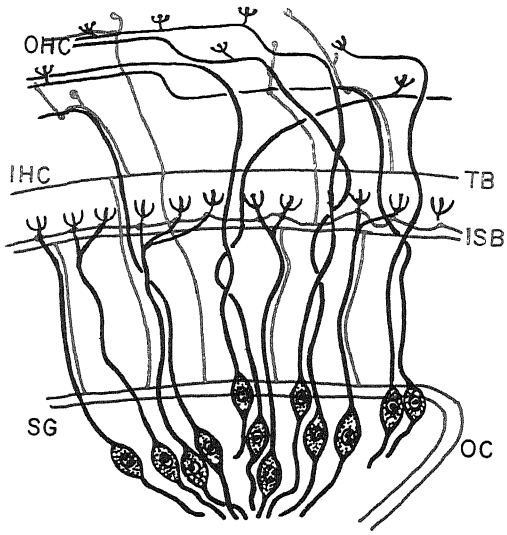

Fig 8 18 Schematic illustration of the innervation of cochlear hair cells Afferent fibers are in solid black lines efferent fibers are represented by brown lines OHC outer hair cells IHC inner hair cells SG spiral ganglion OC olivocochlear bundle ISB internal spiral bundle ESB, external spiral bundle TB tunnel bundle (Smith and Rasmussen 1963)

while the larger type may be as large as 5 μ long and 1 to 3 μ in diameter and is densely filled with vesicles Electronmicroscopy reveals presynaptic bars under the plasma membrane of the hair cells where it is in contact with the smaller endings The membrane adjacent to the larger endings is characteristic of a postsynaptic relation

The smaller endings are believed to be afferent, while the larger ones are believed to represent the terminations of efferent fibers from the olivocochlear bundle Rasmussen (1960) has identified about 500 of these efferent fibers in the cat and observed terminations on both inner and outer hair cells The relative courses of cochlear and vestibular efferent fibers are illustrated in Figure 8 19 Bipolar cell bodies of the afferent neurons are located in the spiral ganglion, within Rosenthal's canal of the modiolus Central to the ganglion they form the cochlear nerve trunk, fibers of which terminate on the dorsal and ventral cochlear nuclei

RESPONSE CHARACTERISTICS OF SINGLE UNITS

It is of considerable interest to know the way in which individual nerve cells of the auditory nerve bundle respond to various frequencies of stimulation of the ear The first experiment to report the responses of single units was that of Galambos and Davis (1943) Using microelectrodes, they obtained responses from single fibers and explored the way in which the discharge frequency varied as a function of the frequency of stimulation From such records it was possible for them to plot response area functions for the individual units (Fig 8 20) Units were found to have a single "best" frequency at which they would respond with minimum sound pressure With increase in the sound power of the stimulating source, these units showed a widening range of frequency over which they would respond Characteristically, when plotted on a logarithmic scale, the response area function showed a steeper front toward the higher frequencies This suggests that the increased range of frequencies with increased sound pressure was gained largely in the direction of lower frequencies Some correction must be made for the logarithmic scale, however Nonetheless, one might expect a greater increase in the frequency of response toward reduced frequencies by reason of the fact that increased amplitude will result in an extension of the motion of the basilar membrane toward the apex, the direction which will bring in those hair cells which presumably are responding to low frequencies

Subsequent findings (Galambos and Davis, 1944) of inhibitory processes placed in question the original conclusion that recordings had been made from the primary auditory nerve fibers The nature of inhibitory processes is still not entirely clear, however, and the demonstration of inhibition did not necessarily indicate that the source of original recordings was secondary cells of the cochlear nucleus rather than the fibers of the auditory nerve

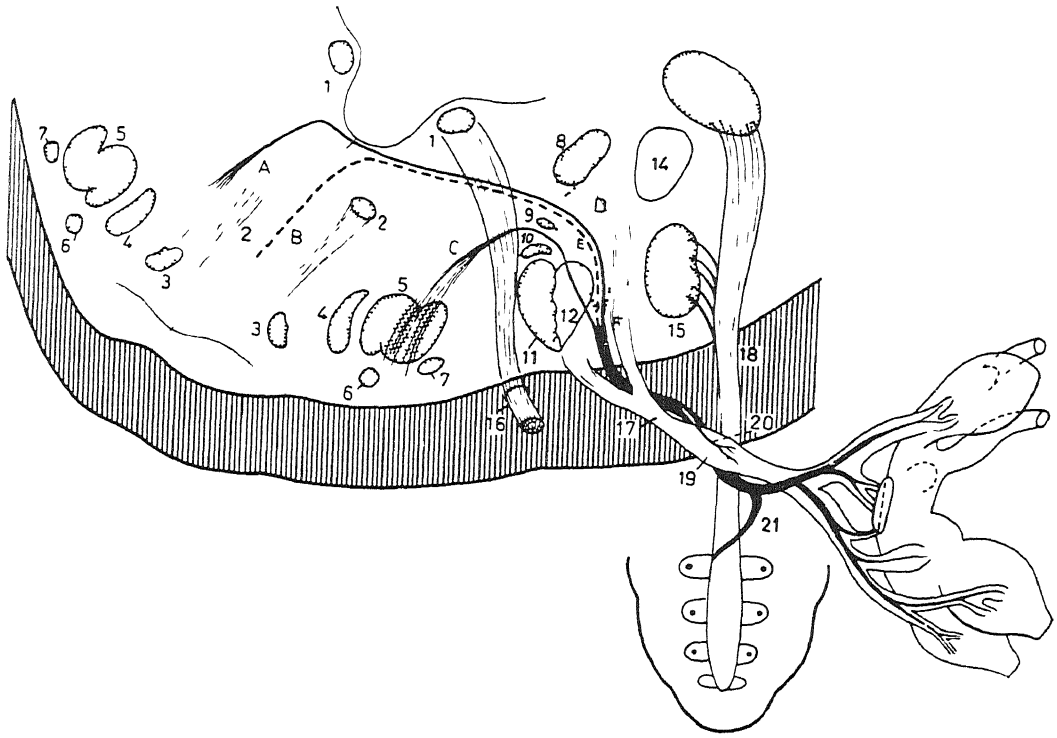

Fig 8 19 Cochlear and vestibular efferent systems A crossed cochlear efferent bundle B uncrossed reticulocochlear and reticulovestibular bundle C uncrossed cochlear efferent bundle D and E dorsal and ventral uncrossed vestibular efferent bundles F bundle containing all of the efferent cochlear and vestibular fibers 1 facial genu 2 abducens 3 trapezoid nucleus 4 medial superior olivary nucleus 5 lateral superior olivary nucleus 6 medial preolivary nucleus 7 lateral preolivary nucleus 8 lateral vestibular nucleus 9 interposed vestibular nucleus 10 inferior vestibular nucleus 11 nucleus of descending root of trigeminal 12 descending root of trigeminal 13 dorsal cochlear nucleus 14 inferior cerebellar peduncle 15 ventral cochlear nucleus 16 facial nerve 17 vestibular division of N VIII with superior and inferior roots 18 cochlear division of N VIII 19 ganglion of Scarpa 20 efferent fibers to Scarpa s ganglion 21 vestibulocochlear anastomosis of Oort (Rossi 1965)

Subsequently, large numbers of recordings have been made from single fibers in the auditory nerve in the cochlear nucleus by Tasaki (1954), Katsuki and his associates (Katsuki, Sumi, Uchiyama, and Watanabe, 1958, Katsuki, Suga, and Kanno, 1962) and by Kiang (1966) The response area curves plotted against a logarithmic frequency scale were found to be both symmetrical and asymmetrical with a steeper front toward higher frequencies in the latter case The symmetrical units were less common than asymmetrical ones It has not been possible to demonstrate specific associations of symmetrical units with the different receptors of the cochlea Response areas appear broader for lower frequency units

The finding of response areas with characteristic best frequencies distributed over the entire range of frequency response for the ear studied is a powerful argument for the encoding of frequency information in the auditory system in terms of the individual fibers or patterns of fibers excited It has, therefore, been of interest to examine the frequency response characteristics of units higher in the auditory nervous system in order to ascertain the extent to which this type of coding is retained, as information is transmitted to the primary auditory regions of the cortex

NEURAL ANATOMY OF THE AUDITORY SYSTEM

Afferent fibers, which mediate the transmission of responses of the receptor cells within the organ of Corti after entering the medulla in the cochlear nerve, divide and send branches to the dorsal and ventral cochlear nuclei (Fig 8 21) A number of second order neurons pass from these to the superior olivary

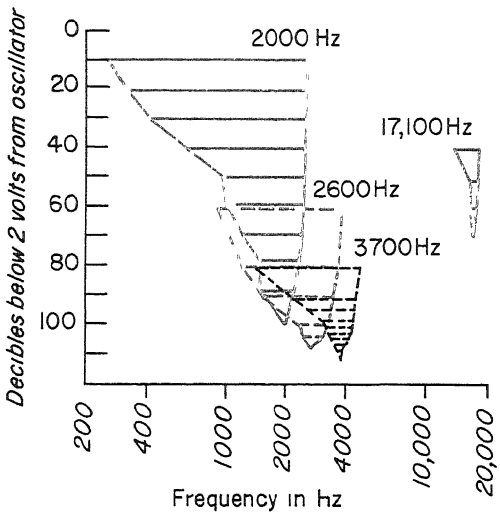

Fig 8 20 Response areas of four neurons in the cochlear nucleus of the cat Each neuron has a specific frequency at which a minimal acoustic energy is required to excite it Each responds also to progressively lower frequencies at higher intensities There is a slight extension of the range of response into higher frequencies but the cut-off is much sharper on the high frequency side Some distortion of the shape of these cut-off functions as a result of the logarithmic frequency plot must be taken into account (Galambos and Davis 1943)

nuclei on both sides from *each* side of the medulla Other fibers ascend to the lateral lemniscus directly, terminating in its dorsal nucleus or extending on to the inferior colliculus At each of these levels there appears to be crossing by fibers from one side to the other There is thus representation on each side of the brain of fibers carrying signals which have originated in each ear Fibers from the inferior colliculus ascend to the medial geniculate nucleus ipsilaterally From this station in the medulla, fibers pass to the primary auditory cortex via the internal capsule In addition to the direct pathway described, there are also additional reflex connections with various cranial motor nuclei The fact that a cat with complete transection of the classic auditory pathways at the level of the midbrain can be aroused by loud sounds suggests a secondary route to the cortex, perhaps via the reticular formation of the midbrain

Laterality of the Auditory System. Although anatomical pathways are available to both sides of the brain from each ear, there is some evidence that crossed pathways play the dominant role (Rosenzweig, 1951, Kimura, 1961b) Thus, the right ear provides better access to the left hemisphere and the left ear provides better access to the right hemisphere In a variety of experiments, evidence has been found for selective hemispheric processing of auditory inputs depending on their nature Language related sounds are usually processed by the left hemisphere and other sounds are processed predominantly by the right hemisphere Evidence for this comes from simultaneous presentation of different sounds to the two ears In the case of speech sounds, such as digits or consonant-vowel combinations, the sound presented to the right ear is retained more frequently when competing sounds are presented to the two ears (Kimura, 1961a, Broadbent and Gregory, 1964) The reverse is true for nonspeech sounds, such as music (Kimura, 1964) and sustained vowel sounds or tonal sounds (Shankweiler and Studdert-Kennedy, 1967) These findings are supported by studies of patients with damage to the right and left temporal lobes Left temporal lesions are associated with poorer performance in the recognition of digits than right temporal lobe lesions Performance in the reporting of digits presented to either ear is affected by left temporal lobectomy, but not by right temporal lobectomy (Kimura, 1961a) In some individuals, the right hemisphere may be dominant for language, in which case the left ear provides a more ready access for speech sounds (Kimura, 1961b)

Efferent Pathways. In addition to the ascending pathways, descending pathways from the cortex have been described (Desmedt, 1962) Fibers which terminate on both the cells of origin of the olivocochlear bundles and on the neurons of the ventral cochlear nucleus have been identified The olivocochlear bundle originating in the superior olivary nucleus is an efferent pathway from which the efferent fibers terminating on hair cells arise The identity of the efferent fibers and the afferent fibers has been ascertained by sectioning of the olivocochlear bundle, in which case efferent fibers degenerate If the acoustic nerve is sectioned, afferent fibers degenerate These procedures permit the identification of which nerve terminals are which in the region of the hair cells (Engstrom, Ades, and Hawkins, 1965a) The precise function of the efferent pathways is not clear, but an inhibitory role has been assigned to them (Galambos, 1956)

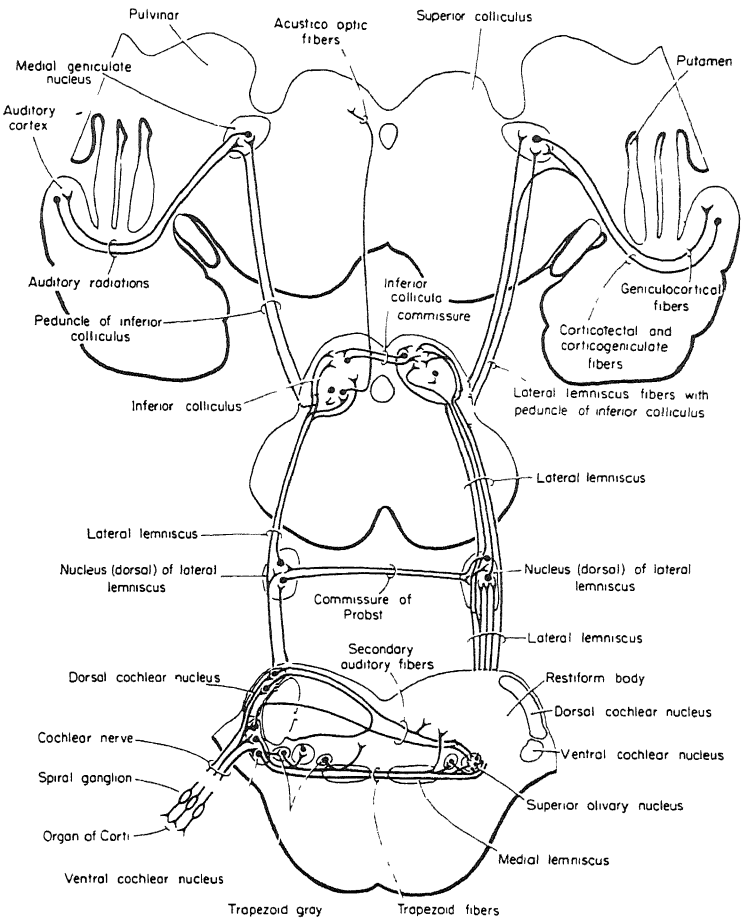

Fig 8 21 Major central pathways of the auditory system (Crosby Humphrey and Lauer 1962)

VARIATION OF FUNCTION AT DIFFERENT NEURAL LEVELS

Response areas have been studied in all parts of the auditory nervous system (Fig 8 22) It is evident that the frequency coding of single units is maintained up to the level of the inferior colliculus At this point there are a number of relatively narrow response areas with best frequencies distributed over the entire auditory spectrum Katsuki has argued (1961) that this type of coding is maintained up to the level of the medial geniculate body, but the evidence does not appear to be as good at this level, even considering Katsuki's own work Whitfield argues (1967) that tonotopic organization is of little consequence at levels higher than the inferior colliculus On the other hand, Erulkar has argued (Erulkar, Nelson, and Bryan, 1968) that some tonotopic organization persists up to the level of the cortex with a variation in selectivity depending upon the cortical layer from which recordings are made

Surveying all of the evidence, it is clear that the nature of response of single neural units changes from the auditory nerve up to higher centers with good frequency coding up to the level of the inferior colliculus, and relatively poor frequency coding beyond this point toward the auditory cortex In addition, there is a relative decrease in the correlation between the intensity of the stimulus and the frequency of discharge of single units as one ascends in the system There would appear to be a significant change in the nature of coding from the level of the inferior colliculus up to the cortex This is discussed further below

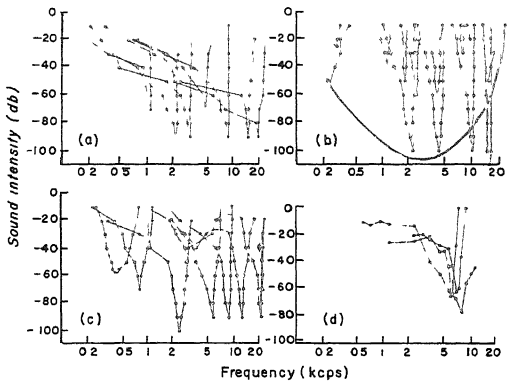

Fig 8 22 Response areas of single neurons obtained from *a*) cochlear nerve *b*) inferior colliculus *c*) trapezoid body and *d*) medial geniculate body of the cat (Katsuki 1961)

INHIBITORY PROCESSES

Inhibition is recognized as playing an important role in all sensory systems Several different kinds of inhibition have been observed in the auditory system Some of these originate in the peripheral mechanism itself and others may have their origin at higher levels of the auditory nervous system Any reduction in the level of activity of a single fiber or unit which accompanies stimulation is defined as inhibition This may result by the presentation of a single tone which serves to reduce the spontaneous firing rate of a unit not otherwise stimulated (Ruppert et al , 1963, Allanson and Whitfield, 1955) Another way of demonstrating inhibition may be to reduce the activity resulting from the effects of continuous tone stimulation by the presentation of a second stimulus (Frishkopf and Goldstein, 1963) Under these circumstances, the inhibitory signal may be one to which the unit would show no response at all, or it may be one to which there would be a positive response in the absence of any other input stimulation The results of a variety of investigations do not provide good agreement on the precise nature of these inhibitory processes No inhibitory effects below 1000 Hz. have been reported by Nomoto et al (1964), while Sachs and Kiang (1968) report two-tone inhibition effects at frequencies as low as 200 Hz The latter investigators report that, when tested appropriately, all fibers in the auditory nerve appear to show two-tone inhibition On the other hand, they found no evidence for suppression of spontaneous activity in any of the units which were tested with a single tone (Fig 8 23) Here, positive response areas are seen to be bounded by inhibitory regions which intrude slightly into the positive response area Within the inhibitory regions, stimulation suppresses activity elicited by an exciting stimulus

The function of these inhibitory processes may be to provide a sharpening of the frequency selectivity of the system (Greenwood and Maruyama, 1965) Erulkar, Gerstein, and Butler (1966) report more evidence for inhibitory processes up to the level of the inferior colliculus than within the cortex Their work is based on intracellular recording of the inhibitory postsynaptic potential

Most of the inhibition discussed above probably arises out of neural interactions among peripheral neural elements It has been suggested, however, that two tone inhibition could result from mechanical interaction in the basilar membrane (Simmons, 1970)

There is another mechanism for inhibition quite different from those described above This results from the activity of efferent fibers of the olivocochlear bundle, arising in the superior olivary nucleus and innervating, contralaterally, hair cells of the organ of Corti Galambos (1956) has demonstrated that stimulation of the olivocochlear bundle via the floor of the fourth ventricle may reduce the whole nerve response by as much as would a 15- 20-db drop in stimulus intensity At the same time, such stimulation may be accompanied by an enhancement of the cochlear microphonic potential (Desmedt, 1962, Fex, 1962)

POSSIBLE BINAURAL MECHANISMS

Some units respond to stimulation of the two ears with differences in latency The magnitude of the latency difference is of the appropriate order of magnitude for the difference in time of arrival of a sound pressure wave at the two ears when the source of the sound is located off to one side of the listener The presumption is that these cells would be maximally excited by sound originating in just such a location For such a unit, a sound on the opposite side of the body would result in the units being relatively refractory at the time of excitation of the distal ear Such units could thus serve in binaural localization (Erulkar et al , 1968) Erulkar has also found units for which the nature of the frequency response area differs between the two ears What function such units may serve is unclear

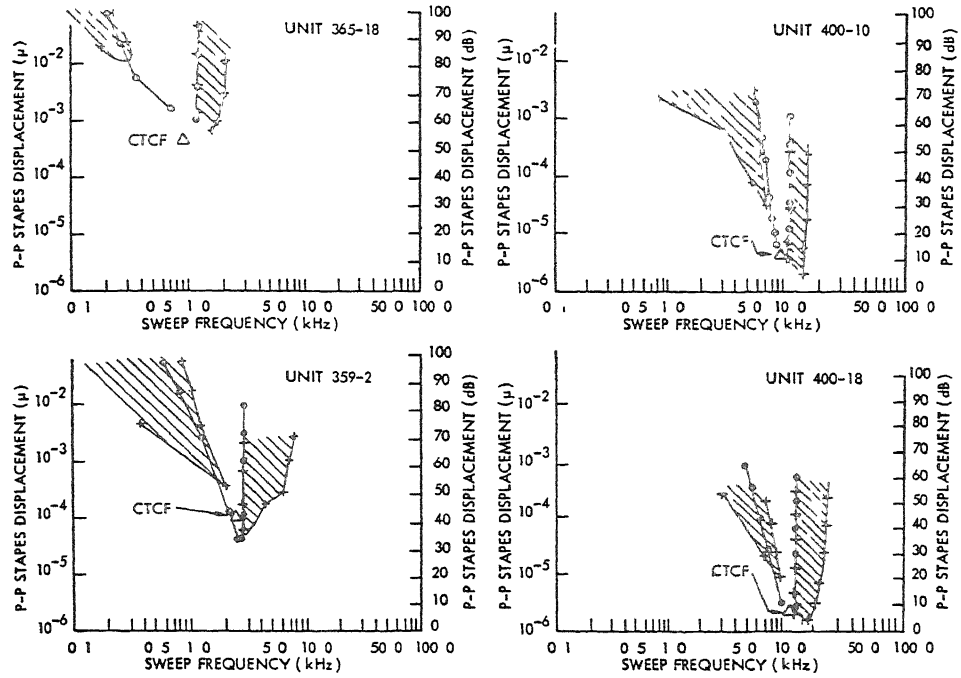

Fig 8 23 Response and inhibitory areas for four fibers in the cat auditory nerve The characteristic frequency (CTCF) is marked by a triangle and represents that frequency to which the unit is most sensitive The boundary of the response area marked by dots is defined by the amplitude of a sweep frequency which results in an increase in rate by 20% over the level of spontaneous activity Ordinate axes represent peak-to-peak stapes displacement in micra and in decibels The hatched areas represent frequencies and amplitudes in which the sweep frequency reduces the response rate by 20% or more below the rate obtained with the characteristic frequency alone These inhibitory areas are defined by presenting the critical frequency continuously along with the sweep frequency the latter varying exponentially in time between two frequency values which differ by one or two decades (Sachs and Kiang 1968)

THEORIES OF AUDITORY INFORMATION PROCESSING

The adaptive role of the auditory mechanism in man or animals is to provide information concerning the environment Sound is an important dimension for warning, searching, identifying, and signalling As a medium of communication, it is at its most complex in human speech To understand the mode of function of any sensory system, attempts are often made to determine ways in which it permits the encoding of simple physical dimensions of the stimulus for transmission to the brain for analysis and interpretation A weakness of this approach is that it often begins with the selection of certain stimulus dimensions, considered in their simplest form, and the evaluation of how these influence the nervous system when varied parametrically In audition, this has lead to great concern with the encoding of frequency information As suggested earlier, this may not be unreasonable in view of the fact that complex sounds can be synthesized by the combination of appropriate sinusoidal components It is possible however, that such endeavors have been overemphasized Nonetheless, work on the processing of frequency information has been useful It has demonstrated a relation between the response of specific neural units and the frequency of the stimulus and, at low frequencies at least, some relation between temporal periodicities of the stimulus and the response

These relations are clearly less pronounced at higher auditory centers In human voice communication, relatively little information is transferred on the basis of simple frequency coding Speech sounds, for example, have a recognizable identity by reason of the relative temporal variations among their frequency components The actual frequencies involved are relatively unimportant compared to the relations among them Two voices, representing different frequency ranges, can com-

municate the same word with the same meaning with no danger of misinterpretation The identity of the word clearly depends upon relations which are independent of specific frequencies (Garrett and Fodor, 1968) The identity of the word and its recognizability are also quite independent of its loudness, provided that loudness is above a certain minimum level for the conditions of background noise which prevail

What may serve best for analysis then, is a system which includes elements that will respond to selected temporal variations among components of a stimulus where relative frequencies are of greater importance than absolute values Many of the cells of the auditory cortex seem to respond in just this way While peripherally there is clear tonotopic organization of the system, with specific fibers responding maximally to specific frequencies of stimulation and specific cells of the cochlear nucleus in the inferior colliculus doing likewise along with physical arrangement of units in locations which show some relation to their frequency response, this kind of organization is far less pronounced in higher centers, particularly in the cortex With ascent in the auditory nervous system beyond the inferior colliculus, there is a decrease in the relation between the frequency of neural activity and the intensity of the stimulus, and a decrease in the extent to which single units are associated uniquely with a "best frequency" Some tonotopic organization persists in the cortex (Hind, 1960), but it is greatly reduced At the level of the medial geniculate nucleus, many cells may respond only to the onset of stimulation or to its offset At the level of the auditory cortex investigators have been frustrated by an inability to find any appropriate stimulus for a number of units which can be detected by their spontaneous discharge In anaesthetized animals, Erulkar, Rose, and Davies (1956) found 34% of the units studied totally unresponsive In unanaesthetized animals, Galambos (1960) found 18% unresponsive He was able to characterize the response of approximately 70% of the cells studied in terms of the optimum frequency of pure tone stimulation, but other investigators have not found as high a percentage as this Whitfield and Evans (1965) report that 21% of cortical units respond only to "odd" sounds such as the jingling of keys, and that a significant percentage cannot be stimulated at all Units which respond to change in frequency or amplitude have been found, and some of these are sensitive to the direction and rate of change of frequency (Erulkar, Nelson, and Bryan, 1968) Some units of this sort have been reported in cochlear nucleus cells, but they are much more common in the cortex Such units must be a focus of converging fibers from peripheral regions which represent a range of frequencies, and possess temporal response characteristics which vary systematically with their frequency response characteristic It is possible that the nature of cortical connections is determined during development, after birth, and is influenced by the nature and relevance of the stimuli to which the organism is exposed Appropriate stimulation for many of the cortical units that have been detected by reason of spontaneous discharge has simply not been found It would be impossible to explore all of the logical stimulus possibilities in the laboratory, there are too many of these (Erulkar et al , 1968)

Another characteristic of the nervous system which renders it difficult, if not impossible, to arrive at a definitive statement as to how it works is its great flexibility Animals which have been trained to make discriminations based on frequency of auditory stimulation show a disruption of their performance after ablation of the auditory cortex, yet they are able to relearn such discriminations following ablation Thus, such discriminations can be mediated by other, probably lower, centers (Neff, 1961) Initial disruption of the performance argues for some cortical role under normal conditions, and it is possible that discriminations learned after ablation are based on neural cuing systems which never operate in a normal animal. It is of course possible that the initial disruption is a sequel to the operative procedure and that pitch discriminations are characteristically made at lower levels in the nervous system

Cortical ablation does disrupt certain kinds of performance irrevocably Any complex temporal discriminations, such as those based on the pattern of repetition of two tones, cannot be relearned in the absence of the cortex It therefore is reasonable to conclude that the most important discriminations made by auditory mechanisms, such as the recognition of speech sounds, do in fact depend upon cortical function Some understanding of how this

complex system may work has just begun to develop There are some interesting analogies between the auditory mechanism and the visual mechanism

Basic Auditory Functions and Hearing Impairment

PSYCHOLOGICAL STUDIES OF HEARING

A variety of properties of the auditory mechanism of man has been studied by psychophysical procedures (Licklider, 1951, Tobias, 1970) These include studies of the way in which characteristics of the stimulus must be varied for a listener to make some sort of discrimination for a given set of background stimulus conditions, or for a listener to make a judgment of equality for some specific dimension between two different stimuli An example of the latter might be the loudness of two tones of different frequency The results of such experimentation provide us with valuable information on the nature of the function of the auditory mechanism, and they are also of practical concern for the testing of this mechanism in order to discover evidences of impairment

Work of this kind has been extended in another class of investigation in which listeners are asked to make magnitude estimations or to adjust stimuli for ratio changes with respect to some dimension For example, a listener might be asked to set the intensity control of an oscillator such that a given tone has a loudness twice as great or half as great as that of a tone heard in an interval preceding the time at which the setting is to be made In general, studies based on a simple discrimination task or on an equality judgment provide more reliable results, but all of the results of investigations of this sort are of interest and provide a basis for further insights into the nature of the function of the auditory system

Absolute Threshold. The smallest amount of sound power that the ear can detect in any given frequency is necessarily a statistical concept Attempts to measure such an amount produce variable results which are influenced by differences in the subjects of the test, differences from time to time in a given subject, and a variety of procedural factors Nonetheless, minimum sound power levels must be selected which can serve as a standard representative of a large population of normal listeners. Two functions which are representative of the minimum threshold in sound pressure are illustrated in Figure 8 24 including the recent international audiometric zero curve (ISO, 1964) which serves as a current standard

Differential Thresholds. Differential thresholds, at least for the discrimination of intensity differences, may be considered as an extension of the absolute threshold determination when the background is changed from one of quiet to one with a controlled continuous sound level In many sensory modalities it has been demonstrated that there is a rough relation between the level of intensity increment necessary for discrimination and the intensity level of the background against which the discrimination is to be made This relation is known as the Weber-Fechner Law, but is really only an approximate description over a limited range of the variables which may be studied In audition, the intensity increment required for discrimination at background levels near threshold is relatively large but declines in relative amplitude up to a background level of approximately 50 db above threshold The situation is complicated by the fact that the size of the increment also varies with the frequency of the sound

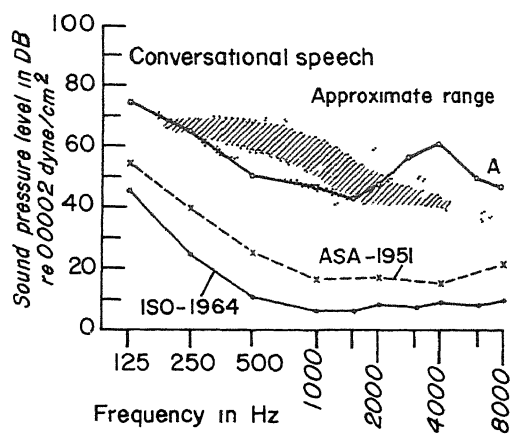

Fig 8 24 The newly adopted International Audiometric Zero (ISO-64) curve compared with the American Standards Association (ASA) 1951 curve The ISO curve represents a better approximation of the thresholds of normal young adults than does the ASA 1951 curve The shaded area indicates the pressure-frequency region in which most conversational speech sounds occur Curve A represents thresholds typical of a case of moderate hearing impairment (Davis 1965)

When the change in frequency of a sound necessary for discrimination of the fact that frequency has been changed is studied as a function of frequency, there is an approximately constant ratio between the frequency increment and the reference frequency above 1000 Hz The absolute increment in frequency is roughly constant at 2 or 3 Hz from 60 to 1000 Hz for sound pressure levels above 30 db A three-dimensional plot of this latter relation is illustrated in Figure 8 25, with sensation level in decibels as the third parameter

The nature of the frequency response of the human ear can be examined from the level of threshold for detection of sound at a given frequency up to the maximum comfortable level of sound stimulation by obtaining data on the matching of loudness at a variety of levels over the entire frequency spectrum These relations are illustrated in Figure 8 26 Each curve is labeled in accordance with the sound pressure level in decibels at 1000 Hz It is clear that there is considerable flattening of the frequency response with increase in intensity level and hence, loudness This is particularly true at the low frequency end of the spectrum The rate of growth of loudness with increased intensity is thus much greater at very low frequencies The same loudness increase occurs over a much curtailed range of intensities This is also true to a lesser extent at the highest frequencies It is more difficult to obtain data at these high frequency levels for a large number of subjects It is clear that no simple metric for the addition of loudnesses of different frequencies is practical It is impractical not just because of the nature of the data displayed in Figure 8 26, but also by reason of the fact that when differing sound components are added they retain their individual identity to a large degree The listener is able to make some discrimination of the individual components of complex sounds In addition, if frequencies added are sufficiently close together they may produce beating phenomena which further complicate the situation

Masking. From our discussion of differential thresholds for sound intensity, it is clear that with elevation of a background sound the increment which can just be discriminated must also be increased The background sound thus serves, to a degree, to mask the increment The phenomenon becomes more complex when one examines the masking effects of various frequencies on a given frequency or the

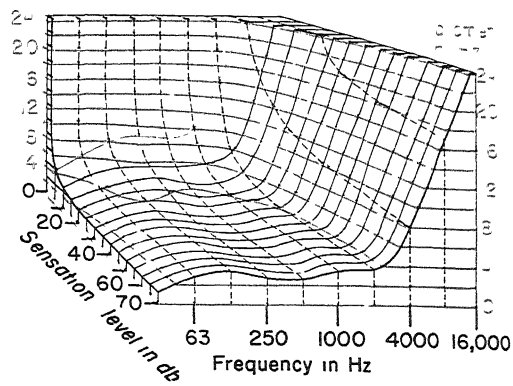

Fig 8 25 Three-dimensional surface showing the standard frequency discrimination threshold as a function of the frequency and the intensity of a standard tone Frequency discrimination is poor at intensity levels near absolute threshold in the rear of the figure and at high frequencies in the extreme right of the figure For frequencies below 1000 Hz at sensation levels above 30 db frequency discrimination requires a change of only about 3 Hz (Licklider 1951)

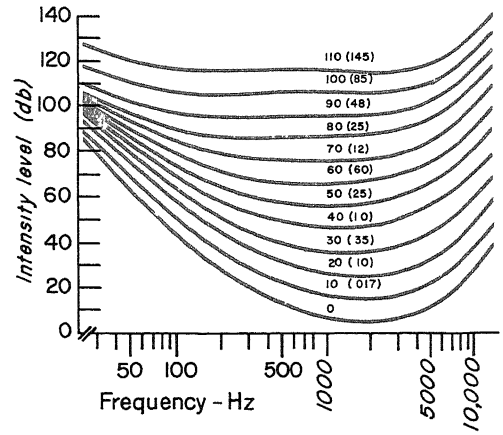

Fig 8 26 Equal-loudness contours showing the relation between intensity level and frequency at various subjectively equated loudness levels The figures 0 to 110 represent loudness level in phons a loudness scale based on equal loudness judgments with the intensity level in decibels of 1000-Hz tone as a reference The lowest curve approximates the normal free-field threshold curve Figures in parentheses show loudness in sones a scale based on subjective ratio estimates The latter scale presumably provides a better indication of subjective magnitudes of loudness (Stevens and Davis 1938)

effects of a wide band of frequencies or noise on a given frequency In general, masking is more effective the closer the frequency of the masking tone to that of the tone being masked, although the precise nature of the relation here may be complicated by the beating

phenomenon Low frequency tones mask high frequency tones more effectively than the converse The latter effect might be expected from our knowledge of the motions of the basilar membrane Interestingly enough, and of some practical significance in the measurement of hearing disability, there is relatively little masking effect when a masking tone is presented to one ear and a test tone to the other This phenomenon is useful in suppressing the better ear when one wishes to test an ear in which unilateral hearing impairment is suspected A fairly broad spectrum noise serves as a useful mask for a wide range of frequencies in these circumstances

Loudness. As illustrated in Figure 8 26, it is possible to make judgments of the equality of loudness, even though the frequency of the tones so equated differs The specification of loudness level is conveniently accomplished by the use of equal loudness contours (Fig 8 26) The intensity level in decibels of a 1000-Hz tone is taken as a reference Loudness level is expressed in *phons* and is equal to the intensity level in decibels of the 1000-Hz tone which matches any other frequency for which the loudness is to be designated

Binaural Cues for Sound Localization A listener is able to estimate the location of origin of a sound moderately well There are several obvious physical cues which may serve to explain this ability in anyone possessed of two normally functioning ears In the first place, a sound originating on one side of the body will reach one ear first and hence, there will be a time delay between stimulation of that ear and the other ear For continuous tones, there will be a difference in the phase relation between the two ears which will depend both on frequency of the stimulating tone and the physical dimensions of the head In addition, the sound reaching the more distant ear may be attenuated The head will serve to cast a sound shadow for the ear on the side away from the point of origin and this will reduce intensity on that side, particularly for sounds of higher frequency

Differences in time or phase are probably of most importance for frequencies below 1400 Hz , while at higher frequencies differences in intensity probably represent the most important cue The higher the frequency, the greater will be the attenuation of sound in the shadow of solid objects past which it is transmitted In careful studies of sound localization, it has been determined that very small displacements of a sound source from the median plane through the head can be discriminated, while much grosser displacements are necessary for the discrimination of a change in point of origin when the sound is directly off to one side or the other Sounds which are directly in the median plane are very difficult to localize as to whether they are in front of, behind, or above the listener Particularly in these circumstances, movements of the head play a very important role in the localization of a sound source It is clear that the changing pattern of intensity between the two ears will be directly opposite for a sound located in front of the head as contrasted with one in back of the head when the head is turned from side to side On the other hand, for sounds which are directly overhead, there will be almost no change at all The absence of any change with head movement is thus a cue to the location of the sound overhead

As anyone who has enjoyed sterophonic music reproduction can testify, there is more to binaural hearing than simple localization Hearing of complex sounds, such as music, the sources of which are distributed in space, is greatly enriched when they are heard with two ears The best stereophonic reproduction is only a gross approximation of this but is nonetheless quite a pleasing phenomenon Two arbitrarily located microphone positions serve to divide the relative balance of the sound which is reproduced in two arbitrarily located loud speakers Optimum effect is achieved when the listener is located in the appropriate relation to the two speakers, and they in turn have a relation which is appropriate for the original method of recording A precise duplication of binaural listening might be achieved by locating two microphones on either side of a dummy head and feeding the sound recorded under such circumstances to a listener via earphones Unfortunately, under these circumstances the changes which one comes to expect with slight movements of the head would not occur.

TYPES OF HEARING IMPAIRMENT

The causes of deafness are divided into five classes (Davis, 1951) In the first of these, there is some interference with the conduction of sound to the neural mechanism of the inner ear. Hearing difficulties resulting from these causes are labeled *conduction deafness* The

second category is that resulting from damage to the cochlear mechanism or the auditory nerve and this is labeled nerve deafness The other three classes include *central deafness*, *diplacusis* or a false sense of pitch which may be caused by edema of the labyrinth, and *tinnitus* associated with ringing in the ears which is usually caused by hypersensitivity of hair cells or their nerves

Conduction Deafness. Conduction deafness may be caused by such a simple problem as the accumulation of wax in the external ear canal It is more significant, however, when it occurs by reason of such factors as the pathological hardening of the tympanic membrane, perforation of that membrane, or a loss of mobility or destruction of part of the ossicular chain A small perforation of the drum is often temporary and may heal, but dysfunction of the ossicular chain requires some kind of intervention for its correction In *otosclerosis*, there is a growth of bone which may tend to freeze the footplate of the stapes such that it is unable to transmit motion to the oval window of the scala vestibuli Initial effects may be manifested by a progressive loss of hearing for the low frequencies with possible subsequent loss in high frequency which accompany pathological changes in the cochlea itself

Over the last several decades, there has been an evolution of operative procedures for the correction of deafness resulting from middle ear dysfunction In the earliest operation, Lempert's fenestration procedure, a new window was made from the middle ear cavity to the lateral bony semicircular canal This served to bypass the immobile bone link and partially restore the hearing loss An improvement was achieved by the development of a procedure for mobilization of the stapes by Rosen (Schuknecht, 1962) The method often produces dramatic and immediate improvements in hearing but suffers from the fact that there is a fairly high rate of recurrence of the difficulty The newest procedure is one in which the entire stapes is removed and its footplate replaced by a vein graft or pad of fat over the oval window A linkage to the long process of the incus is accomplished by the use of a wire of plastic prosthesis In cases of hearing deficiency which are the result of chronic *otitis media*, the appropriate procedure may be *tympanoplasty*, the surgical reconstruction of the entire sound-conducting system of the middle ear The precise nature of this operation will vary with the nature of the impairment

A variety of acute effects may result in hearing impairment Several of these cause conduction deafness If the eustachian tube is blocked for any reason during a rapid change in ambient pressure, the balance of pressure between the external meatus and the middle ear will be upset If the middle ear pressure is low and cannot be compensated, as would be the case during descent in aircraft, the drum membrane may be strongly retracted and the conduction efficiency of the system greatly reduced Rupture of the drum will not occur unless the pressure differential reaches the range of 100 to 500 mm of mercury The problem is perhaps more frequently encountered by the diver during descent into deep water A pressure differential which can cause rupture of the drum can easily be reached, but it will generally be preceded by warning pain which will result in the diver's ascent before rupture occurs In spite of the warning which pain provides, transient injury to the drum is a frequent problem for overzealous skin divers

If the eustachian tube remains closed for any length of time, the air trapped in the middle ear is gradually absorbed The lowered partial pressure of oxygen in the cavity may be accompanied by the entrance of fluid into the middle ear when gas pressure falls below hydrostatic pressure in the capillary bed The accumulated fluid increases friction and decreases the transmission of sound

Nerve Deafness. The most common cause of sensorineural impairment is probably exposure to high level sound intensities (Graham, 1966) As mentioned above, there is a temporary shift in threshold (TTS) after exposure to a loud sound or noise (Fig 8 27) If the sound is loud enough and the period of exposure is long enough or repeated frequently enough, the elevation of threshold may be permanent In general, sensorineural deafness affects hearing for higher frequencies to a much greater extent than low frequencies and there appears to be a particular vulnerability in the region of 4000 Hz This may result from the physical nature of the cochlear mechanism which mediates response to sounds of this frequency When caused by exposure to high level sound, such deafness is bilateral When the shift in threshold is of the order of 40 to 60 db , the

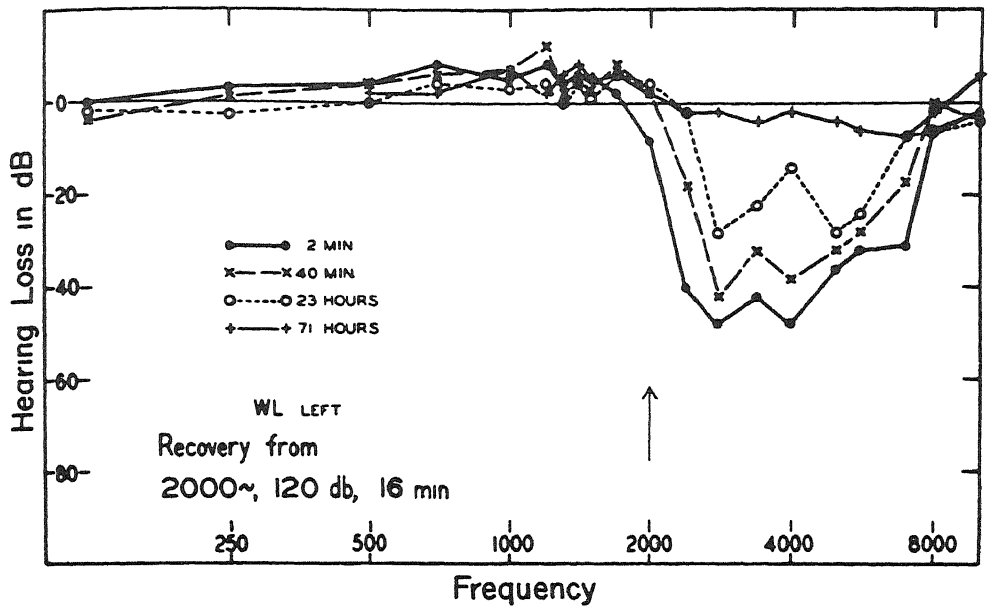

Fig 8 27 Temporary threshold shift (TTS) after exposure to a tone of 2000 Hz at 120 db sound pressure level for 16 min Recovery is shown over the course of time up to 71 hr after exposure Note that the shift of threshold is greatest for frequencies above that of the exposure tone (Davis et al 1950)

loss may be accompanied by *tinnitus*, a sustained ringing sound which is attributed to spontaneous discharge of injured hair cells

Hearing loss associated with injury to the hair cells is accompanied by the phenomenon of *recruitment* That is, at the frequencies of greatest impairment there is a more rapid growth of loudness than normal (compare the rapid growth of loudness in the normal ear at low frequencies) such that the balance of sounds over a broad range of frequencies, including the range of impairment, may be normal at higher sound intensities (Fig 8 28) If sensorineural impairment is the result of infection, it may be unilateral Menière's syndrome is accompanied by hearing loss in the low frequencies, and by sometimes violent attacks of vertigo This probably is the result of an involvement of the other sensory elements in the labyrinth as well as the cochlea Tumors may cause auditory impairment in a variety of ways depending on their location and extent They are not associated with recruitment, however

Finally, just as vision appears to show progressive degradation with increased age, so does hearing (Fig 8.29), particularly for higher frequencies Fortunately, the discrimination of speech depends primarily on frequencies between about 500 and 3000 to 5000 Hz Therefore, the characteristic high frequency loss with increasing age causes only a minimum of difficulty in most circumstances (French and Steinberg, 1947)

A relatively new hazard to hearing results from the specific action of drugs of the streptomycin group on the labyrinthine mechanism They cause degeneration of the hair cells, which may occur even more rapidly for the vestibular apparatus than for the organ of Corti Such drugs have been useful experimentally for pharmacological labyrinthectomy

THE MEASUREMENT AND DIAGNOSIS OF HEARING IMPAIRMENT

Audiometry. The standard clinical tool for the measurement of hearing, the audiometer, consists of an oscillator for the production of selected frequencies usually ranging from 125 to 12,000 Hz , an amplifier, an attenuator or volume control, and headphones which can be driven individually or with various balances of excitation The output of the oscillator is adjusted at each of the frequencies such that when the attenuation control is set at zero, the output of the headphones represents a signal corresponding to the sound pressure level of a

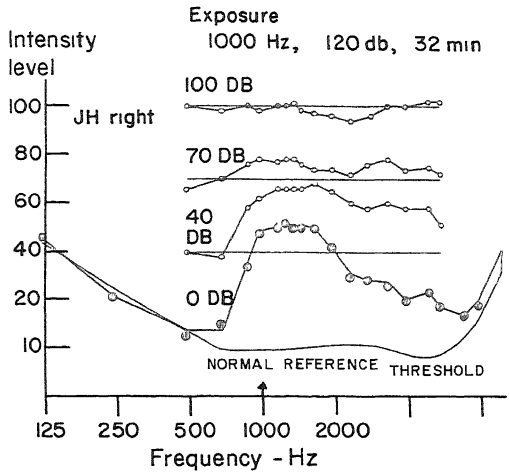

Fig 8 28 Intensity levels required for a match of loudness over the frequency range from approximately 125 to 8000 Hz following exposure to a 1000-Hz tone at 120 db sound pressure level for 32 min Loudness matches are shown for each of four levels relative to the 1000 Hz normal reference level 0 db 40 db 70 db and 100 db Note that there is virtually no elevation of the intensity level required in the frequency range affected for the 100-db level and relatively little effect at the 70-db level (Davis et al 1950)

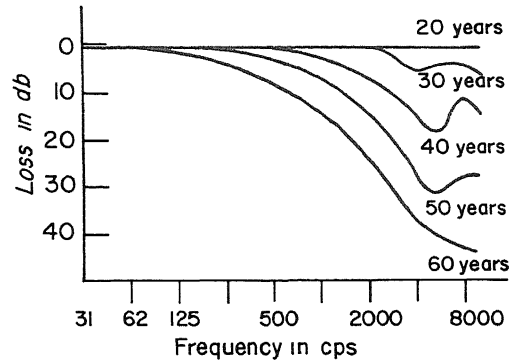

Fig 8 29 Progressive loss of sensitivity at high frequencies with increasing age The normal audiogram at 20 years of age serves as a reference for the losses represented at greater ages (Licklider 1951)

standard reference curve (see Fig 8 24) The attenuation control is usually calibrated in 5-db steps An increase in the reading of the attenuation control corresponds to an increase in the sound power level at the headphones by an equivalent amount Thus, if an appropriate attenuator setting can be determined at which a subject just hears the tone at a given frequency, then the reading of the attenuator control represents the sound power level over a normal standard which is required for that patient at that frequency An audiogram can then be plotted which represents hearing loss at each of the selected frequencies in terms of the increased sound power required in decibels as compared with the normal level The examiner need not concern himself with the specific form of the frequency response of the ear The device is compensated for this and provides for a direct measurement of loss relative to the appropriate reference at each frequency tested

There are a variety of procedures for testing hearing with an audiometer (Jerger, 1963) A fairly simple one for most patients is the presentation of tones continuously at a level slightly above threshold The continuous tone is interrupted at random intervals by the examiner The patient is instructed to signal the interruption of the tone by depression of a switch which causes a light to come on on the instrument panel The whole procedure has been automated in a device designed by von Bekésy in which the patient holds a button depressed as long as he hears the tone and releases it when he is unable to hear the tone Depression of the button drives the output of the oscillator down Output increases at a regular rate when the button is not depressed The frequency spectrum is swept slowly from 100 to 10,000 Hz and a recording pen traces the upward and downward changes in intensity corresponding to the subject's manipulation of the switch The midpoint between reversals of direction of the pen may be taken as a reasonable representation of threshold Examples of audiograms obtained with the conventional procedure are shown in Figure 8 30, a von Békésy audiogram is illustrated in Figure 8 31

Several methods have been developed for the testing of hearing without the requirement for any instruction or special performance on the part of the patient One of these depends upon an *electrodermal response* (EDR) or change in resistance of the skin which follows a mild electric shock The shock is regularly paired with the testing tone until it comes to evoke the EDR, even before shock is presented In another test, the electroencephalographic response recorded from scalp electrodes provides an indication of whether a tone has been heard Responses are evoked in the electroencephalogram by sound stimulation for

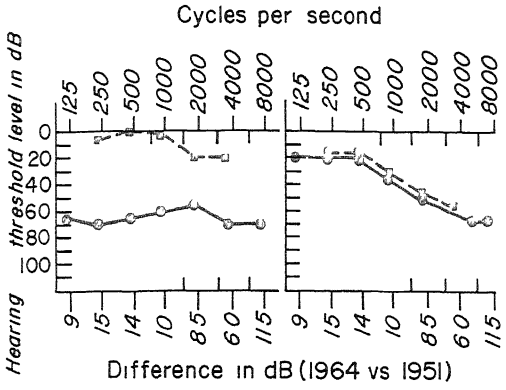

Fig 8 30 Audiograms illustrating conductive impairment of hearing on the left and sensorineural impairment of hearing on the right The solid curve is for air conduction the dashed curve for bone conduction Note that bone conduction and air conduction curves are quite similar in sensorineural impairment

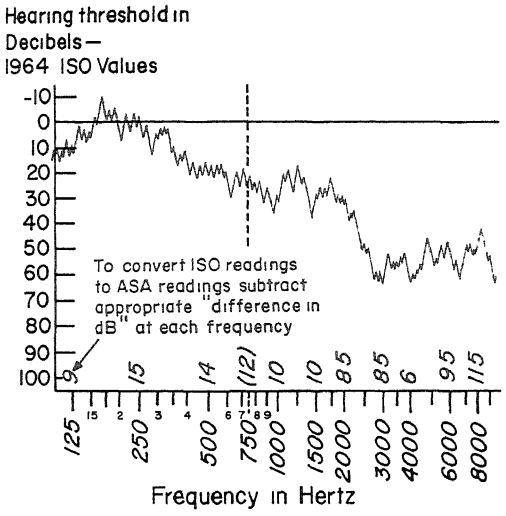

Fig 8 31 A von Bekesy audiogram of a middle-aged patient with some sensorineural impairment attributable to cumulative effects of quinine ototoxicity repeated experimental exposures to sound at 120 to 140 db sound pressure level and advancing age

appropriately placed electrodes, and a skilled operator may determine threshold values by the interpretation of such records

Bone Conduction Tests. A variety of procedures is available which assist in the diagnosis of hearing impairment In addition to the headphones used with an audiometer, a small vibrator may also be used This is placed either on the forehead or on the mastoid prominence behind the ear Vibrations of the skull are transmitted to the cochlea and oval window directly For frequencies up to about 1500 Hz , the nature of suspension of the ossicles in the middle ear is such that they do not tend to move with skull vibration Thus, there is a relative motion between the footplate of the stapes and the oval window Sound is heard just as it would be if the stapes itself were vibrating At higher frequencies, the skull does not vibrate as a rigid body but rather in sections As vibrations are transmitted to the bony walls of the cochlea, the contained fluids are set in motion and hair cells are stimulated With either mechanism of bone conduction, the pathways of the external meatus and the middle ear are bypassed Thus, a loss which may be registered when measurements are made with air conduction by reason of conduction deafness will not appear Of course, account must be taken of the lower efficiency of the bone conduction pathways to the inner ear The difference in threshold may be anywhere between 30 and 60 db , depending on the conditions of measurement A special attenuation scale is often included on a clinical audiometer which differs from the scale employed with headphones by approximately 30 db , at least over a limited range of calibrated frequencies The audiograms illustrated in Figure 8 30 provide an example of the diagnostic value of employing both air conduction and bone conduction measurements In the curve on the left, a near normal audiogram is obtained by bone conduction while there is a better than 60 db attenuation with air conduction Clearly, the nature of the impairment here involves conduction to the inner ear On the other hand, in the figure on the right, the roughly equal impairments demonstrated by air conduction and bone conduction signify some form of sensorineural involvement Problems may arise in testing unilateral deafness with bone conduction techniques Sound may be conducted around the head to the good ear when the bone conduction vibrator is located on the mastoid bone behind the impaired ear The patient can then provide a correct report as to the presence or absence of the tone near normal levels in spite of his impairment This problem is overcome by presenting a masking sound to the good ear As indicated above, the contralateral effect of masking is relatively minimal The appropriate masking level may be adjusted on the basis of comparative meas-

urements of air conduction thresholds in each of the ears When the good ear is masked, bone conduction thresholds can confidently be made on the impaired ear

Diagnosis of Recruitment Recruitment, or an abnormally rapid increase in loudness with increase in sound intensity, can be demonstrated in cases of unilateral hearing impairment by permitting a patient to adjust the balance control of the audiometer so that the sound heard appears to be in a medial plane or centered in the head When the loudness is equal for the two ears, this will be the case At very low levels, it will be necessary to increase the excitation in the phone over the impaired ear with respect to the level of excitation in the phone over the good ear As the sound level is raised, the amount of imbalance decreases until at somewhere in the neighborhood of 70 db the imbalance may be completely eliminated

Other Tests of Hearing Impairment There is a variety of relatively simple diagnostic tests of hearing impairment which can be made with nothing more complicated than a tuning fork At the other extreme, techniques for the measurement of the impedance presented by the external canal of the ear with its termination at the tympanic membrane have been developed These permit the identification of changes which result from pathology involving the drum or the ossicular chain Application of a loud sound to the opposite ear will elicit a reflex contraction of the stapedius muscle of the ear under test which, in the normal ear, will result in a characteristic change in the measured impedance Recruitment may be observed if a normal stapedius reflex is obtained at a relatively high stimulus level in spite of an elevated threshold

Speech Audiometry For practical purposes, particularly the extent to which understanding of speech may be affected by a hearing loss, the absolute threshold for the entire range of frequencies may be of little concern and even the absolute threshold in that range of frequencies which is most important for the discrimination of speech may be of little importance As mentioned above, in certain types of sensorineural deafness, there is a recovery of loudness up to near normal level with increase in the intensity of a sound above threshold, even at a frequency where there may be gross impairment based on threshold determinations For this reason, a variety of tests of hearing based on the recognition of spoken words has been developed Selected test words may include spondees, words of two

Table 8 2
Classes of hearing handicap ISO–1964

db	Class	Degree of Handicap	Average Hearing Threshold Level for 500, 1000, and 2000 Hz in the Better Ear		Ability to Understand Speech
			More than	No more than	
	A	Not significant		25 db (ISO)	No significant difficulty with faint speech
25					
	B	Slight handicap	25 db (ISO)	40 db	Difficulty only with faint speech
40					
	C	Mild handicap	30 db	55 db	Frequent difficulty with normal speech
55					
	D	Marked handicap	55 db	70 db	Frequent difficulty with loud speech
70					
	E	Severe handicap	70 db	90 db	Can understand only shouted or amplified speech
90					
	F	Extreme handicap	90 db		Usually cannot understand even amplified speech

From Davis (1965b)

syllables which are equally stressed, or monosyllabic words Lists of words are presented to the patient from phonographic or tape recordings such that the loudness can be standardized and controlled Performance is based on the number of words that can be repeated correctly at various intensity levels Lists of words are selected to include appropriate representation of the various speech sounds in conversational English The percentage of the words which the patient is able to repeat correctly is his discrimination score or articulation score An index of the adequacy of hearing for normal social interaction may be derived from such scores (Davis, 1965)

In the absence of elaborate tests of hearing which involve the spoken word, the elevation of threshold at frequencies of 500, 1000, and 2000 Hz provides a useful indication of the significance of the impairment (See Table 8 2)

HEARING AIDS

Hearing aids improve the conduction of sound to the inner ear They may thus be useful in aiding someone with a conduction deafness or even with sensorineural impairment when the resulting deafness is not complete No effort is made to match the response characteristics of the hearing aid to the frequency response characteristics of the loss of the patient Such "prescription" correction has not been found to be of any benefit With severe sensorineural defects, there may be little benefit derivable from the use of any type of hearing aid

3 / VESTIBULAR FUNCTION

The vestibular mechanism is an extremely sensitive sensory device that provides information as to the nature of movements of an organism and its position in space The sensory receptors of the vestibular system are activated by acceleration forces The semicircular canals are uniquely suited to the detection of angular acceleration components in three dimensional space while the utricles and the saccules are so constructed that they will respond to linear accelerations The utricles are believed to play the predominant role in the determination of the posture of the head under static conditions The stimulus for this kind of discrimination depends upon the orientation of the earth's gravitational acceleration vector with respect to the sensory organ The saccules are richly innervated and in many ways quite similar to the utricles, but their precise function is somewhat uncertain It has been suggested that they may be of most importance for the detection of vibration and possibly very low frequency sound

The vestibular sense does not have the conscious prominence of vision, audition, touch, taste or smell Normally, one is unaware of any vestibular dimension of sensory experience Only with malfunction of the system with resulting dizziness, nausea and other symptoms does the function of the vestibular mechanism attain prominence

Vestibular signals are undoubtedly of great importance for an animal as it moves about in space The control of movements of the entire body, of the head, and particularly of the eyes with respect to the head is refined by feedback signals from the vestibular mechanism in response to bodily movement There are clearly very important species differences with respect to the prominence of the vestibular mechanism Animals which live in three dimensions, such as birds and fish and climbing animals including the cat, have highly developed neural support systems for the vestibular detectors and these animals tend to be dependent to a greater degree than other species on the normal function of this system

We tend to think of the world as we perceive it, at least when we are studying sensory processes, as a world made up of dimensions that correspond to our various sensory systems For man, the vestibular sense hardly has any independent identity by reason of its lack of any conscious concomitant most of the time In fact, our perceptions of the world depend in large degree on interactions among the senses, and the stability of the visual world in particular is dependent upon the coordination of motor responses involving postural mechanisms, the extraocular muscles and sensory information provided by the vestibular mechanism

Anatomy and Physiology of Labyrinthine Systems

COMPONENTS OF THESE SYSTEMS

The extra-auditory portion of the labyrinthine system includes the three semicircular canals, the utricle and the saccule (Fig 8 32) The sensory endings in these structures, located in the cristae of the canals and the maculas of the utricle and saccule, are all innervated by fibers of the vestibular division of the eighth cranial nerve These organ systems are made up of interconnected fluid-filled ducts and sacs which are enclosed in the bony labyrinth within the temporal bone The semicircular canals open at each end to the vestibular chamber in which are located the utricle and saccule This portion of the system is continuous with the auditory labyrinth The entire membranous labyrinth is filled with *endolymph* similar to intracellular fluid and of relatively high potassium concentration Surrounding the membranous system within the bony labyrinthine cavity is the perilymph, similar in composition to the cerebral spinal fluid The nonauditory labyrinth is distinguished from the entire labryinthine system

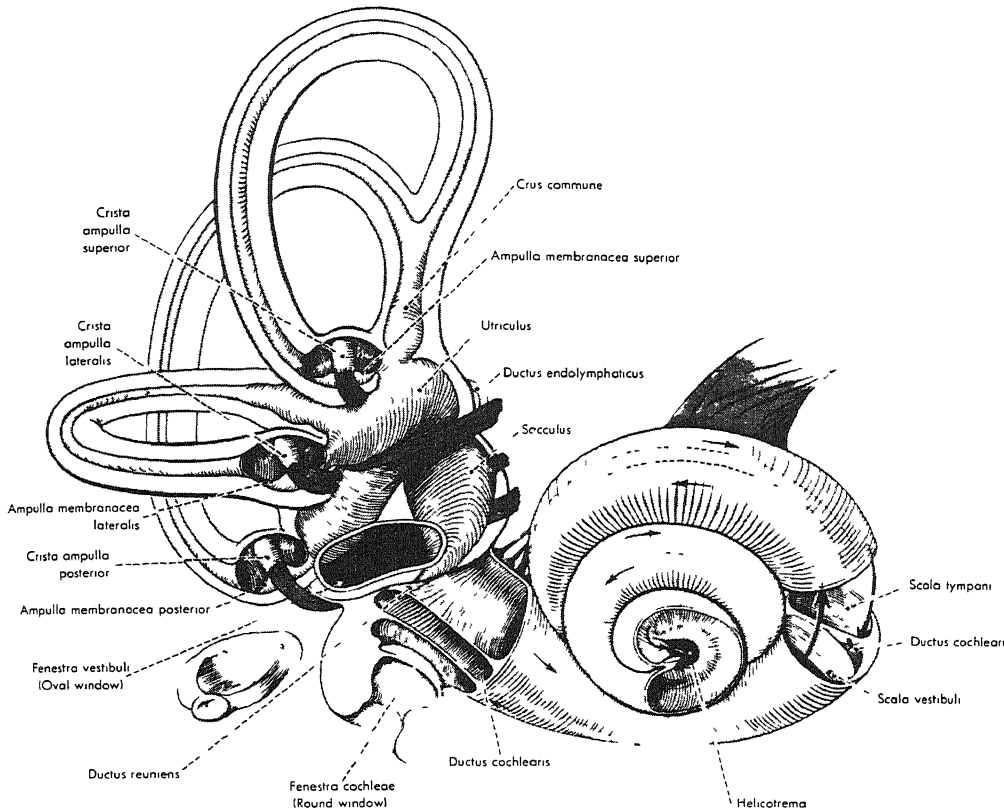

Fig 8.32 A schematic illustration of relations among the semicircular canals the utricle and the saccule and the cochlear duct of the right side The membranous semicircular canals are shown within their surrounding bony structure Nerve connections into the ampullae and the utricle and saccule are shown Various parts of the anatomy of the entire mechanism are identified on the figure (Melloni 1957)

including the cochlea as the *vestibular system* There are several excellent detailed treatments of the anatomy and physiology of this system which provide more information than the present account (Wendt, 1951, Howard and Templeton, 1966, Roberts, 1967)

The Semicircular Canals. The three semicircular canals on each side of the head are oriented in each of three planes which are very nearly perpendicular to each other (Fig 8 32) This arrangement permits response to angular accelerations about any axis in three dimensional space The sensory epithelium of the semicircular canals is located within the ampulla of each canal (Fig 8 33) It is evident (Fig 8.32) that the ampulla of the horizontal or lateral canal, and that of the superior or anterior canal are located close together near the anterior terminations of these canals on the vestibule in the region occupied by the utricle The ampulla of the posterior or inferior canal is proximal to the opposite side of the utricle near the narrow end of the horizontal canal The two vertical canals, superior and posterior, join together in the common crus prior to their entry into the utricular portion of the vestibule

When the head is held erect the horizontal canals are actually inclined downward toward the rear by approximately 30° If the head is tilted forward such that the opening of the external meatus and the outer canthus of the eyelids are on the same horizontal line, then the horizontal canals are very nearly in a horizontal plane (Fig 8 34) Since the anterior canal on one side is in a plane parallel to that of the posterior canal on the other side, the contralateral anterior and posterior canals are maximally stimulated by rotations about a common axis

Stimulation of a given pair of semicircular canals (the horizontal canals in the same plane

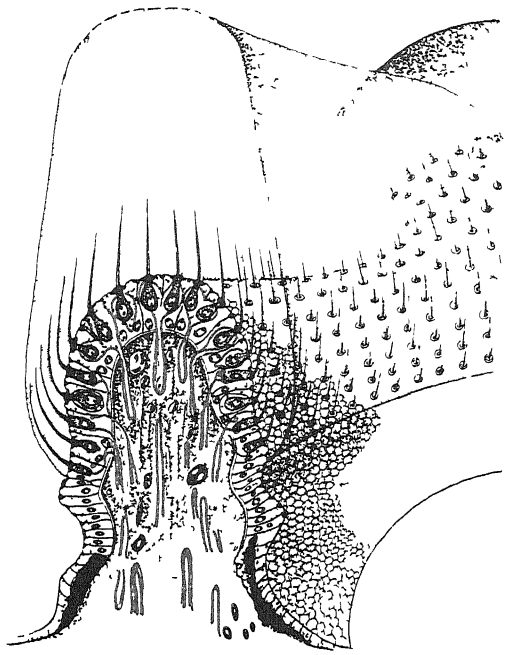

Fig 8 33 Illustration in three dimensions of the crista ampullaris (Wersäll 1956)

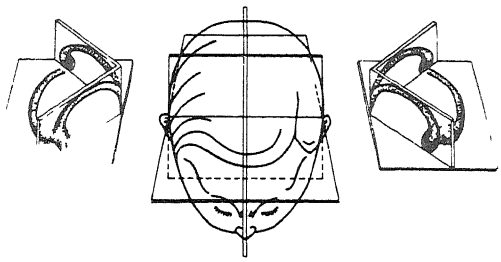

Fig 8 34 Relations of the semicircular canals to the median sagittal transverse frontal and horizontal planes of the head

or vertical canals in parallel planes) occurs whenever a component of angular motion is introduced about an axis which is perpendicular to their plane or planes The mechanism of excitation is bending of the cupula This is caused by the inertial displacement of the endolymph within the membranous canal whenever there is any angular acceleration of the canal The fluid tends to remain stationary as the motion of the canal commences The cupula is thus bent about its point of attachment to the wall of the ampulla as the wall moves at a greater initial rate than does the fluid which the canal contains The cupula, a gelatinous mass extending from the top of the crista to the opposite wall of the ampulla, is in sufficiently close contact with the wall to block the flow of any fluid around it This has been demonstrated by the injection of dye into the canal in fish and the observation that with rotation of the system and bending of the crista and cupula there is no leakage of dye from one side to the other (Steinhausen, 1933) Bending of the cupula causes bending of the hair cells which arise out of the crista and are enveloped in the gelatinous substance of the cupula

If the organism is rotated at a constant velocity, the endolymph within the rotating semicircular canals reaches the same velocity as the rest of the system, although belatedly, and excitation of the receptor endings ceases If the rate of rotation is then reduced, the inertia of the endolymph tends to keep it in motion as the canal slows down and there is bending of the cupula in the opposite direction

Apparently, the mucopolysaccharides which comprise the cupula are secreted by the supporting cells of the crista There are two types of hair cells on the crista (Fig 8 35) The cylindrical type is served by both afferent and efferent nerve endings

Each of the hair cells has from 60 to 100 stereocilia or individual hairs which emerge from its distal surface A single *kinocilium* is located on one side of the cluster of stereocilia The kinocilium is the longest of the cilia and the stereocilia are graded in length with the longest being closest to the kinocilium The two types of hair cells are distributed over the entire surface of the crista, but the bottle-shaped cell (Fig 8 35) is concentrated on the vertex of the crista In the cristae of the horizontal canals, the kinocilia of the hair cells are always located on the side toward the utricle On the other hand, in the case of both the anterior and the posterior vertical canals, the kinocilia are always located on the side of the hair cells away from the utricle It has been demonstrated that bending of the cilia of the hair cells in the direction of the kinocilium results in depolarization of the cells and heightened neural activity Bending in the opposite direction results in hyperpolarization and reduction of the base level of activity (Fig 8 36) Thus, when patterns of motion are such that the endolymph tends to move with respect to the membranous wall of the canals, there will be excitation in the member of a pair of canals on one side of the head and inhi-

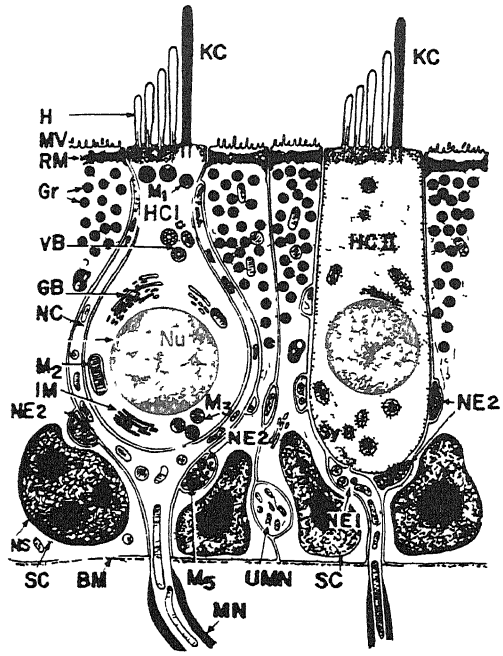

Fig 8 35 Two types of vestibular sensory cells The flask-shaped type I cell (HC I) is surrounded by a nerve calyx (NC) Nerve endings presumed to be efferent (NE 2) make contact with the nerve calyx and directly with the type II cylindrical sense cell (HC II) These cells are supplied by both NE 1 and NE 2 types of nerve endings Several types of mitochondria (M_1 to M_5) are found in the sensory cells and neural elements Additional elements identified in the figure include kinocilia (KC) stereocilia or hairs (H), microvilli (MV) granules (Gr) cell nuclei (Nu) supporting cells (SC) unmyelinated nerve fibers (UMN) myelinated fibers (MN) basement membrane (BM) Golgi complex (GB) synaptic bar (SyB) reticular membranes (RM) intracellular membrane (IM) vesiculated body (VB) and nucleus of supporting cell (NS) (Engström Ades and Hawkins, 1965b)

bition on the other side Rotation of the body to the right about a vertical axis with head erect will cause bending of the cupula in the right horizontal canal toward the utricle or vestibule This will result in excitation The horizontal canal on the left side will be inhibited as its cupula is bent away from the opening into the utricular chamber

Depending upon the orientation of the axis of angular acceleration, the two anterior vertical canals may both be inhibited, both excited, one inhibited and one excited or neither stimulated It must be remembered that they do not operate as a pair, however The anterior canal on one side and the posterior canal on the other work as a pair and they are so arranged that whenever one is excited, the other will be inhibited In the case of both the anterior and posterior vertical canals, rotations which result in bending of the cupula away from the opening into the utricle cause excitation

The lateral selectivity to direction of angular rotation was first established by Ewald (1892), who stated the nature of the response in what is known as Ewald's Second Law The subsequent discovery of the kinocilia and their relative orientations in the different canals provides us with a knowledge of the anatomy which underlies this law (Ewald's First Law stated that the cupula within the ampulla was the site of sensory activation)

The diagonal orientation of the two vertical canals results in both anterior and posterior canal stimulation for rotation about either a transverse lateral or a transverse medial axis Only rotations about an axis perpendicular to the parallel planes of the anterior canal on one side and the posterior canal on the other side

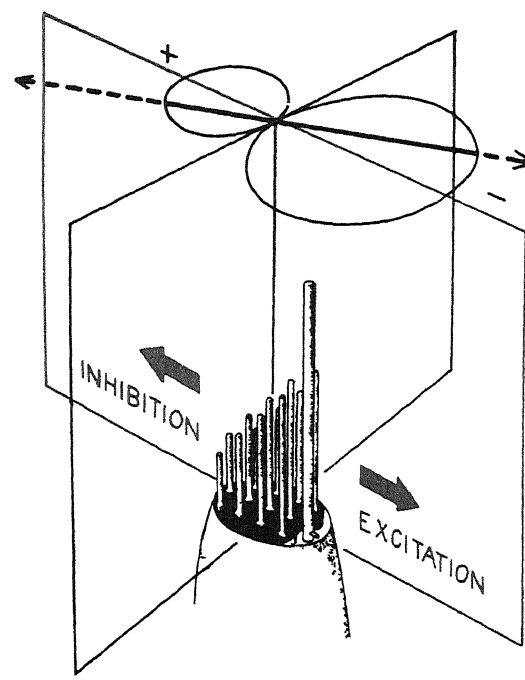

Fig 8 36 The excitation depolarization response which results when hair cells are bent in the direction of the kinocilium or the inhibition polarization response for bending in the opposite direction For a given direction of bending the amplitude of effect is approximated by the length of a line drawn from the point of tangency of the two circles to the intersection of either the circle representing excitation or the circle representing inhibition (Flock 1965)

would fail to stimulate more than one of the vertical canals The backward tilted position of all three of the canals when the head is erect results in excitation of two vertical canals and one horizontal canal for any rotation about a vertical axis The pattern of excitation and inhibition of the six canals is shown in Table 8 3 for rotations about longitudinal, transverse and vertical axes

Excitation of the appropriate canals commences with the beginning of angular acceleration and continues for twenty or more seconds after a constant angular velocity has been reached Neural discharges signaling excitation begin again upon decrease in angular velocity, this time from the opposite canals of the various pairs stimulated by the original rotation Various factors which influence the threshold angular acceleration for neural activity are discussed below Suffice it to say here that the threshold angular rate of acceleration is of the order of ½° per sec ^{2} (Clark, 1967)

The Otolith Organs. The function of otolith organs is fundamentally different from the function of semicircular canals Whereas the latter are excited by reason of the inertial properties of endolymph within the membranous canals, in the otolith organs, stimulation depends upon the difference in density of the otoconia or statoconia, small calcium carbonate crystals, with respect to the gelatinous substrate which supports them The hair cells of the otolith organ are virtually identical with those of the cristae of the semicircular canals Deflection of the hair cells of the otoliths depends upon relative motion of the otoconia with respect to the supporting substrate The cilia of the otolith hair cells are somewhat shorter than those of the semicircular canals (5 to 7 μ) and extend into the gelatinous substrate (Fig 8 37) The specific gravity of the otoconia is approximately 2 94 This is considerably higher than the specific gravity of the supporting structure Thus, the action of a component of linear acceleration on the otoconia results in the exertion of a force for deformation of the otolithic membrane and consequently, possible bending of the hair cells The direction of bending will depend upon the orientation of the resultant acceleration force Terrestrial creatures are continuously subject to the acceleration of the earth's gravitational field and any movement of the head may change the orientation of this acceleration with respect to the otolith organs Thus, the direction of bending of hair cells will vary with head position

Table 8 3
Responses of the six semicircular canals (of fish the thornback ray) to rotation

Semicircular Canal	Rotation about the: Longitudinal axis — Right	Longitudinal axis — Left	Transverse axis — Forwards	Transverse axis — Backwards	Vertical axis — Clockwise	Vertical axis — Anticlockwise
Right anterior vertical	●	⊗	●	⊗	⊗	●
Left anterior vertical	⊗	●	●	⊗	●	⊗

Left posterior vertical	⊗	●	⊗	●	⊗	●
Right horizontal	○	○	○	○	●	⊗
Left horizontal	○	○	○	○	⊗	●

● excited, ⊗ inhibited, ○ unaffected (After Lowenstein and Sand, 1940)

The otoliths have been called static receptors in contrast to the semicircular canals which are called dynamic receptors For a given position of the head, otoconia may exert a force which will maintain hair cells in a bent position, even though the head is maintained stationary In the case of the semicircular canals, a force acts upon the cupula only during angular acceleration At constant velocity of rotation, the cupula returns to its resting position and excitation of the hair cells ceases At least some cells of the otolith organs respond continuously for a given head position There would appear to be a characteristic pattern of nerve fiber activity associated with any specific position of the head

The Utricles. The utricular organ (Fig 8 32) communicates with the saccule by way of the utriculosaccular duct As mentioned above, the circular loop of the semicircular canals is closed through the utricle The macula of the utricle is similar to the crista, with both types of hair cells and supporting cells The cupula is replaced by the otolithic membrane, however, into which extend the shorter hairs of the utricular hair cells The densely packed utricular stones or calcite crystals are embedded in the upper surface of the otolithic membrane The macular surface of the utricle is

Fig 8 37 Bundles of sensory hair cells at the surface of the utricular macula as revealed by the scanning electron-microscope A freeze-drying technique was employed for preparation of the specimen (Engström, 1968)

located on the lower and forward walls of the utricular sac with its posterior two-thirds in a plane approximately parallel to that of the horizontal canal The anterior third is turned up slightly (Fig 8 38) The right and left utricular maculas are in the same orientation and are symmetrical in shape and organization

Unlike the hair cells of the cristae, the hair cells of the utricular maculas do not all have the same orientation with respect to location of their kinocilia Virtually every orientation is represented in each of the macular surfaces The arrows in Figure 8 39 represent orientations of the hair cells over the surface of the

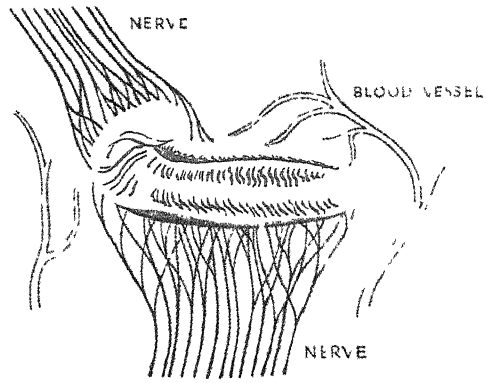

Fig 8 38 The utricular macula of the guinea pig showing separate innervation of its two portions one from the upper and one from the lower division of the vestibular nerve There is presumably also some efferent innervation (Ades and Engstrom 1965)

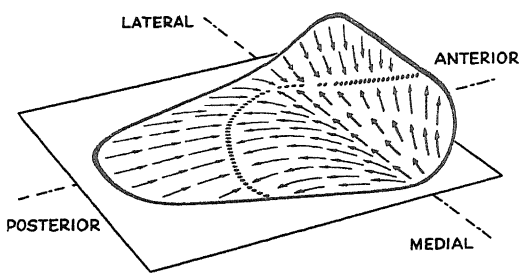

Fig 8 39 The pattern of polarization of sensory cells in the utricular macula of the guinea pig Arrows indicate the direction of bending of statocilia for excitation (Spoendlin 1965)

macula It is evident that tilting of the head from a vertical position in any direction will result in the bending of hairs of at least some of the hair cells in the direction of their kinocilia There would thus appear to be possible a kind of position coding of excitation on the surface of the macula corresponding to the position of the head If the head is tilted backward and down through 150°, most of the otoconia will be pulled out and away from the gelatinous substrate of the macula by the force of gravity As one might expect, under these circumstances, the ability of a human subject to correctly identify his head position in the absence of other cues is least accurate (Brown, 1960) Electrophysiological studies (Lowenstein and Roberts, 1951) have revealed that tilting of the head about any horizontal axis gives rise to activation of the macula of the utricle on either side of the body Individual functional units give maximal responses in accordance with the kind of orientation pattern depicted in Figure 8 39 In addition to the response of the system to the orientation of the linear acceleration vector of the earth's gravitational field, there is a displacement of the otoconia whenever the body is subjected to linear accelerations of any sort under dynamic conditions In addition, rotation about any axis which does not pass through the utricle is accompanied by a linear acceleration component, the instantaneous turning moment of which displaces otoconia and bends hair cells

The dotted line in Figure 8 39, which illustrates the boundary between units of reversed polarity, is also associated anatomically with a boundary between relatively large otoliths on one side and smaller ones on the other (Spoendlin, 1965)

The Saccules. The saccule is connected to the cochlear duct by way of the ductus reuniens The macula of the saccule is located on the medial wall of this cavity in an approximately vertical orientation in an anteroposterior plane The otoliths (Fig 8 40) are lateral, with the macular substrate medial There is a slight concavity of the macular surface as viewed from its lateral aspect on a given side The surface and its shape along with the direction of orientation of the kinocilia of the hair cells are illustrated in Figure 8 41. Unlike the macular surface of the utricle, the hair cells on either side of a line representing a reversal in orientation have kinocilia oriented away from each other rather than toward each other In spite of the striking similarity between the saccules and the utricles, the nature of the function of the saccules is still not understood The nature of the structure of the saccules suggests that they are probably responsive to linear accelerations, but electrophysiological confirmation of any understandable functional role for these organs remains to be accomplished.

NEURAL INNERVATION OF VESTIBULAR EPITHELIA

The diameter of fibers ending on the type 1 hair cells that have the shape of a flask or a chalice (Fig. 8 36) is thought to be, in general, greater than the diameter of fibers terminating

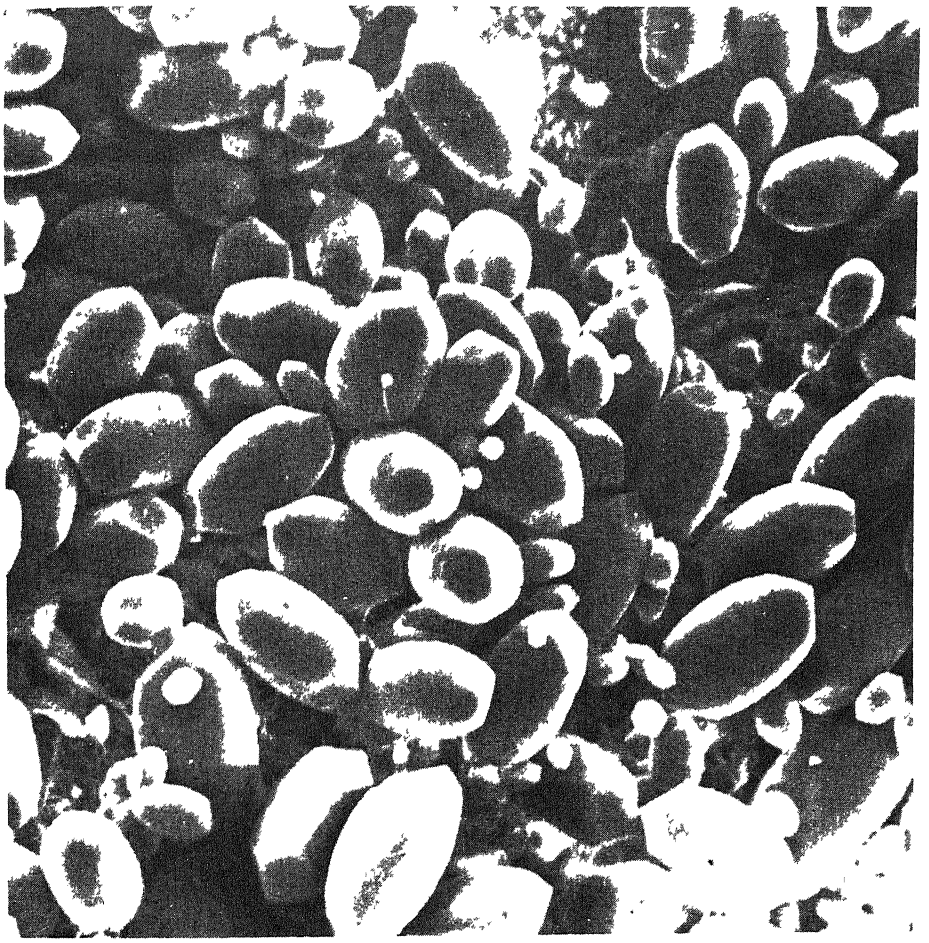

Fig 8 40 Otoconia of the macula of man as revealed by a scanning electron microscope Hexagonal prisms may be discerned clearly in unsectioned material (Photomicrograph provided through the courtesy of Hans Engstrom See Engstrom 1968)

on the cylindrical or type 2 hair cells (Wersall, 1956, Engstrom and Wersall, 1958) It has also been shown, however, that cells of both types may be innervated by branches of the same nerve fiber Innervation of the type 2 cell may come directly from a nerve calyx surrounding a type 1 cell The type 2 cells receive at least two different types of nerve endings The first of these forms a synaptic contact with the hair cell plasma membrane which may be somewhat indented into the cell itself (Engstrom, 1961) These endings are believed to be those of afferent fibers

Another type of nerve ending on these cylindrical hair cells is bouton-shaped, densely granulated and in direct contact with the cell surface There is evidence that nerve endings of this type also contact nerve fibers of the former type at synaptic junctions The chalice-shaped hair cell is almost completely enveloped by a sparsely granulated nerve calix Recent investigations have shown that there are areas where the space between the calix and the cell is reduced which may be associated with a synaptic bar (Ades and Engstrom, 1965) Densely granulated endings of the type associated with the cylindrical cells are found outside the nerve calix (Engstrom, 1961) Collateral branches between the cylindrical and chalice-shaped cells are common Sometimes, several hair cells may be found enclosed in a single chalice (Ades and Engstrôm, 1965)

Studies in which the vestibular nerve or the vestibular nuclei have been transected indicate that the vesiculated nerve endings are efferent

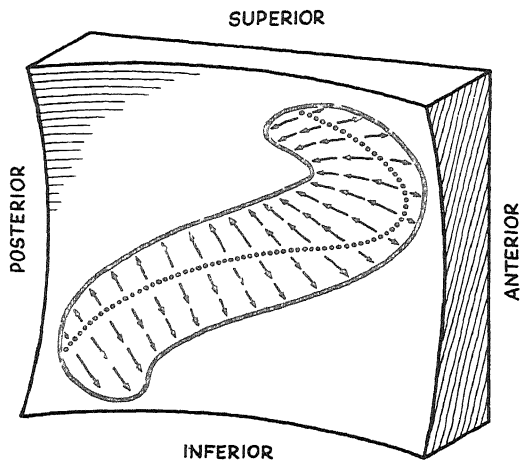

Fig 8 41 The polarization pattern of sensory cells in the saccular macula of the guinea pig Note that although the direction for depolarization is reversed in the region of the middle of the structure as was true for the utricle the direction of bending for excitation is reversed as contrasted with that shown in Figure 10 (Spoendlin 1965)

and that the nerve fibers to which they correspond enter with the vestibular nerve (Smith and Rasmussen, 1963) Selective Wallerian degeneration is most notable in six to ten days after section of the nerve root These fibers show selective staining for acetylcholinesterase which quality is lost after sectioning The fibers have therefore been compared with the efferent fibers to the cochlea in the olivocochlear bundle The efferent fibers apparently form a horizontal nerve plexus which tends to be found in the lower half of the sensory structures (Fig 8 42)

Although there is a difference in density of the neural innervation, the density being greater for the maculas, the arrangements are similar for maculas and cristae At least some of the neurons which give rise to efferent processes appear to be located in the lateral vestibular nucleus (Gacek, 1961) The number of vestibular efferent fibers is estimated to be ap-

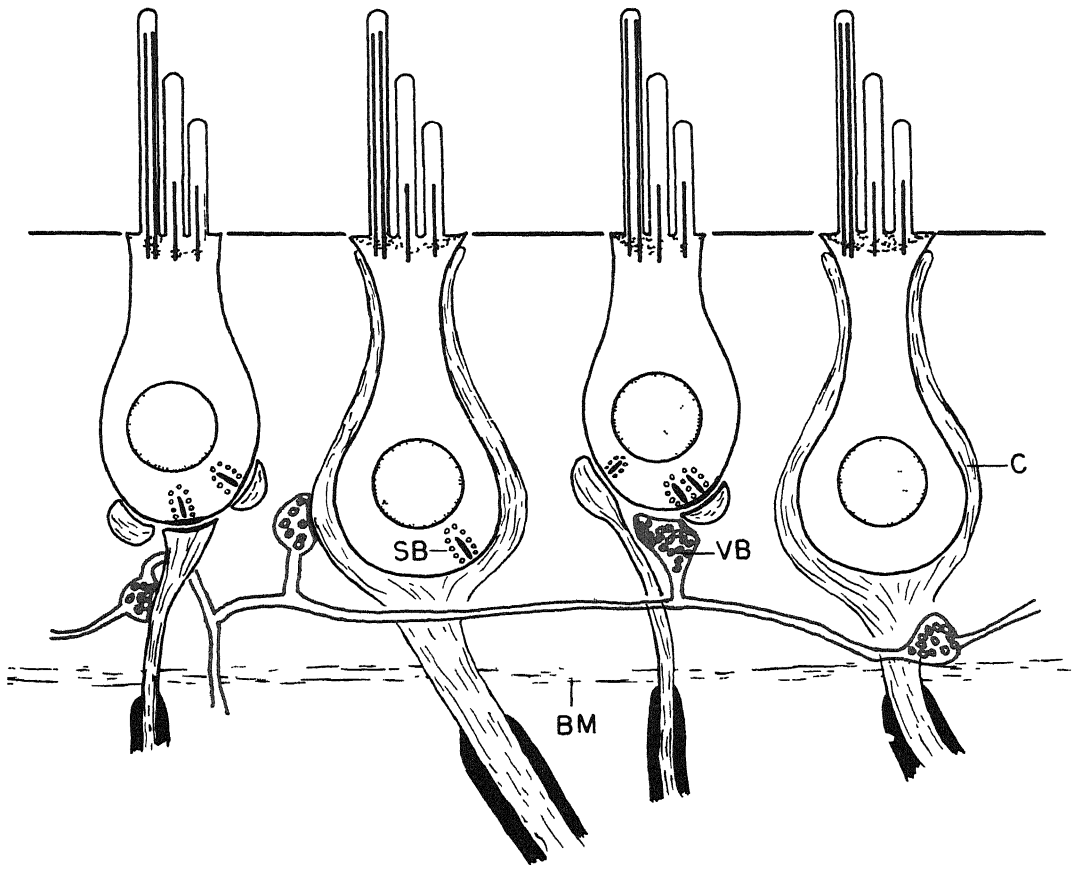

Fig 8 42 Four hair cells and their nerve endings shown in relation to vesiculated boutons (VB) chalice terminals (C) and other boutons and nerve fibers in the chinchilla macula BM basement membrane SB synaptic bar The horizontal plexus is believed formed by efferent nerves (Smith and Rasmussen 1967)

proximately 200 Their pathways are illustrated in Figure 8 43 It is fairly well established that they permit direct inhibitory effects on sensory elements of the receptor mechanism (Sala, 1968, Wersall, 1968)

CENTRAL NEURAL CONNECTIONS OF VESTIBULAR RECEPTORS

Afferent fibers of vestibular receptors are conveyed to the medulla by the vestibular branch of the eighth nerve The cell bodies of the bipolar vestibular neurons are in Scarpa's ganglion within the internal auditory meatus Axons terminate in the superior, lateral, medial and inferior vestibular nuclei of the medulla as well as in the flocculonodular lobe and the fastigial nuclei of the cerebellum Fibers from the superior nucleus join the medial longitudinal bundle on the same side Those from the medial nucleus cross to the medial longitudinal fasciculus on the opposite side Fibers from the inferior nucleus ascend in the medial longitudinal fasciculus on both sides Fibers from these nuclei terminate in nuclei of the third, fourth and sixth cranial nerves They constitute the vestibulo-ocular tract which mediates reflex movements of the eyes (Fig 8 44)

Descending fibers from the inferior nucleus comprise a portion of the spinal extension of the medial longitudinal fasciculus The fibers of the lateral nucleus comprise the descending vestibulospinal tract Postural reflexes involving the neck, trunk and limbs are mediated by these pathways as illustrated in Figure 8 45*A* Connections to the vestibulocerebellar tract are illustrated in Figure 8 45*B* There are a variety of connections between vestibular nuclei and reticular formation which are probably involved in the modulation of flexion and extension responses of the limbs as well as in the activities of other sensory systems

METHODS OF STUDY OF THE VESTIBULAR SYSTEM

A variety of techniques has been employed by physiologists in their efforts to investigate the vestibular system For stimulation of the semicircular canals, rotation is the most appropriate and the most frequently employed procedure (as in the Bárány chair which permits rotation about a vertical axis) Another procedure useful clinically is caloric stimulation Water of a higher or lower temperature

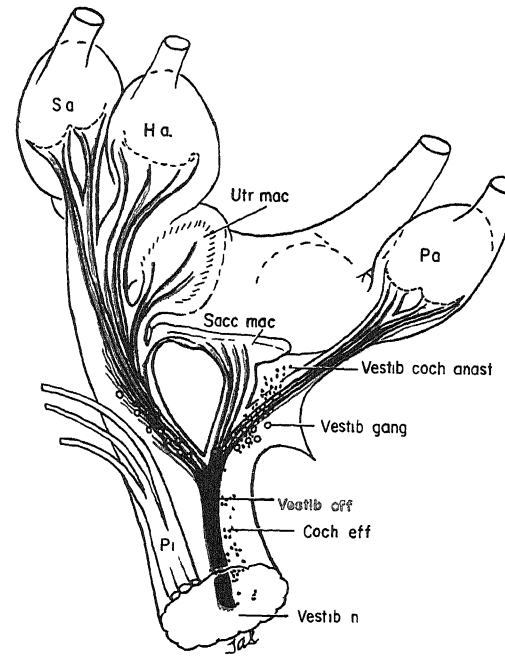

Fig 8 43 Diagram of the vestibular nerve and branches illustrating the course and distribution of the efferent vestibular fibers to the superior ampulla (S a) the horizontal ampulla (H a) and the posterior ampulla (P a) (Gacek 1967)

than body temperature may be injected into the external meatus for varying intervals of time If the temperature gradient is sufficient and a long enough duration of stimulation is employed, the temperature of the fluids of the semicircular canals is apparently raised or lowered in the region of the vestibule resulting in convection currents which serve to stimulate the canals A high temperature solution may be used on one side, and a low temperature on the other to maximize effects On the other hand, one value of the technique is that it permits selective stimulation of the semicircular canal system on one side of the body The supposition that convection currents are in fact responsible for the effectiveness of caloric stimulation is supported by a study which indicates that caloric stimulation is uneffective under conditions of zero gravity (Kellogg and Graybiel, 1967) Without a gravitational force, there are no convection currents

Stimulus. Stimulation of the otolith systems can be achieved by the simple expedient of repositioning the head in the earth's gravitational field Responses associated with otolith organs have also been studied under reduced

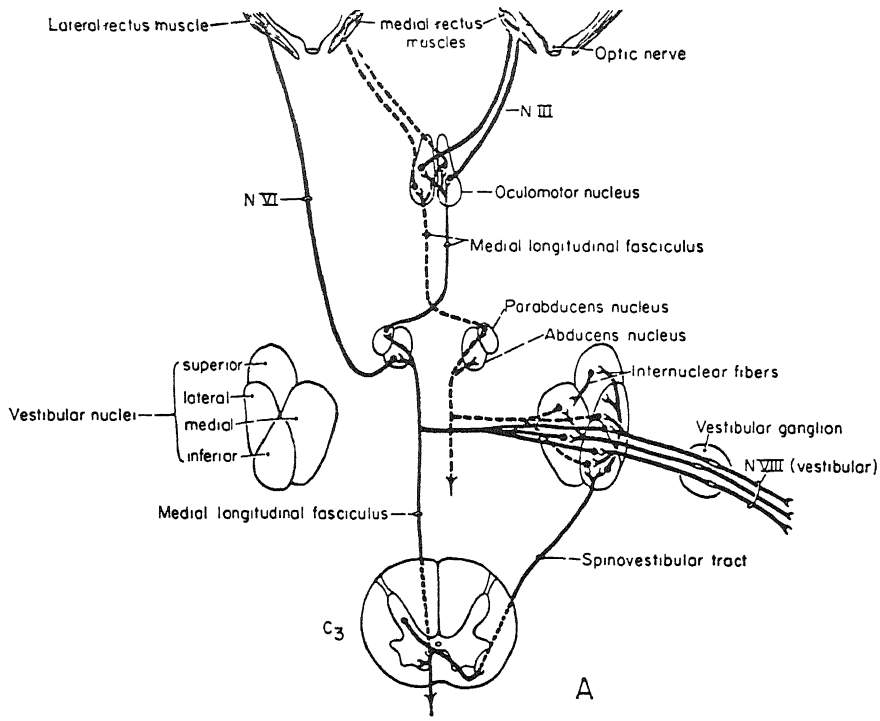

Fig 8 44 Relation of the vestibular nuclei to the medial longitudinal fasciculus and the motor nuclei of the eye muscles for movements in the horizontal plane (Crosby Humphrey and Lauer 1962)

gravitational acceleration in ballistic trajectory flights which can afford brief intervals of zero gravity Effects of increased gravitational force may be investigated on linear accelerators, or on rotating devices with the subject positioned at some distance from the axis of rotation Under these conditions, there is a linear component of centrifugal acceleration which is proportional to the square of the angular velocity and the distance of the subject from the center of rotation Electrical stimulation of the vestibular system has been attempted but the inability to localize such stimulation has rendered this procedure of limited usefulness

Response. Indicators of the effects of vestibular stimulation which have been employed include a number of subjective effects such as the sensation of rotation, the appearance of rotary movements of the visual field, and the impression of tilting or change in orientation of the visual field Motor responses such as the nystagmus motions of the eyes in response to angular acceleration and counterrolling of the eyes in response to a change in orientation of the gravity vector have also proven useful. In addition, there may be gross motor reactions of the body, such as turning of the head or reorientation of the entire body or movements of the limbs in response to angular acceleration Responses within the nervous system have been studied by means of electrical recording from single units in various locations

The importance of a normal vestibular mechanism may be inferred by damaging the mechanism or destroying its function in experimental animals Labyrinthectomies may be produced surgically or the vestibular mechanism may be destroyed by drugs such as streptomycin with specific toxicity for this organ Human subjects with damage to the vestibular mechanism, either from pathology or from the use of toxic drugs have also been of interest in investigation of the system

Psychophysical Studies of Vestibular Function

THRESHOLD DETERMINATIONS

There is a minimum angular rate of acceleration which can be detected by a human subject Under optimum conditions, that rate is

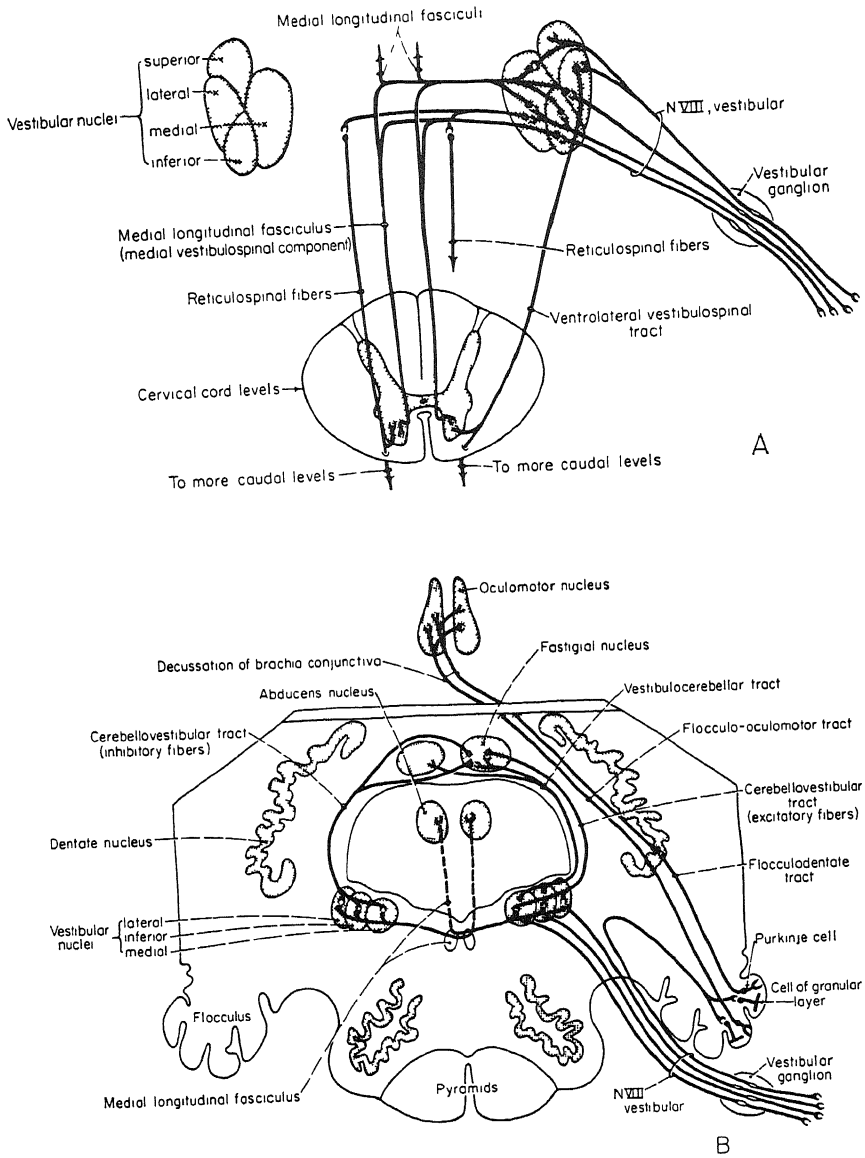

Fig 8 45 *A* Connections between the vestibular nuclei and the ventral horns of the spinal cord *B* Connections between the vestibular nuclei and the cerebellum (Crosby Humphrey and Lauer 1962)

probably of the order of 0 10°/sec ² (Clark, 1967, Clark and Steward, 1968) In order to achieve such low threshold values, it is necessary to employ a reference light point which rotates with the subject Apparently, vestibular imputs to the extraocular muscles in response to the low acceleration result in some eye movement and hence a relative movement of the image of the light spot on the retina which can be detected If subjects are rotated in complete darkness, thresholds of the order of 0 5°/sec ² or slightly lower are reported (De-Vries and Schierbeck, 1953, Meiry, 1966) It is not possible to find agreement on the question of whether certain pairs of canals may have lower thresholds than others (Clark and Steward, 1968). It is rather difficult to orient human observers for the selective stimulation of just one pair of canals

Lowenstein and Sand (1940) were unable to

find axes of rotation which did not produce any response from single fibers subserving the vertical canals in the ray One must be content with the selection of orientations of an axis of rotation with respect to the head which will maximize the stimulation of a given pair of canals Actually, for human subjects, there are no comparable data based even on such approximate maximization techniques for the threshold angular accelerations of selected pairs of canals

The best data available are probably those of Clark and Stewart (1968), which provide thresholds for 18 male subjects with their heads in each of three orthogonal positions with respect to an earth vertical axis of rotation Thresholds were determined with subjects in a seated position, upright, tilted 90° backwards, and on one side with respect to the surface of the rotating platform Results indicated mean thresholds of approximately 0 4°/sec ^{2} for the upright position and the backward tilted position The mean threshold for the side position was 0 67°/sec ^{2} The difference between this latter value and the others was not statistically significant Interaction between otolith excitation and semicircular canal excitation may well complicate the interpretation of results The thresholds reported are for the subjective detection of rotation in the absence of any visual cues whatsoever.

Threshold accelerations for the stimulation of nystagmus may be observed directly or recorded in terms of the electrical signal between two electrodes located on the temples. Such thresholds do not depend upon subjective report and this may be considered an advantage, however, the threshold accelerations for nystagmus are significantly higher than those for either the appearance of movement of a reference spot of light rotating with the observer or the subjective impression of rotation in the absence of any visual cues (Howard and Templeton, 1966)

The otolith organs, particularly the utricles upon which detection of head tilt is believed to depend, may be studied by tilting the body very slowly from an erect posture in a chair device to some position which deviates from the vertical If the rate of tilt is sufficiently slow to prevent stimulation of the semicircular canals, then the question may be asked how much change in orientation of the body with respect to the vertical can be detected by the subject A common procedure for studies of this sort is the presentation of an illuminated line of light, the orientation of which is controlled by the subject If the subject has been tilted to the right or left and is asked to position the illuminated line so that it is in a vertical orientation, then any deviation of the line from the true vertical provides a measure of the extent to which the observer is deceived with respect to the orientation of his own body Probably by reason of the orientation of the utricles within the head, the human subject is most sensitive to slight amounts of tilt away from the vertical As measured by the technique of orienting an illuminated line element, it has been demonstrated that for amounts of tilt of greater than 60° there is a tendency for subjects to underestimate the angle through which they have been tilted while for tilts of less than 60° there is an overestimation of the amount of tilt which has occurred (Miller and Graybiel, 1966) These effects were first reported many years ago (Muller, 1916)

Analogous with the nystagmus response to stimulation of the semicircular canals is the counterrolling of the eyes which occurs when the head is tilted away from the vertical The phenomenon does not lend itself readily to precise threshold determinations, however Counterrolling in the earth's gravitational field is approximately 10° for 60° of tilt away from the vertical No electrical index of counterrolling is readily recordable The dependence of counterrolling on otolith organs, which in turn are dependent upon a gravitational vector, has been demonstrated by studies of counterrolling in response to tilt in normal and labyrinthine defective subjects both on the earth's surface at $1 \times g$ and under zero gravity conditions during flight through a ballistic trajectory in an aircraft Labyrinthine defective subjects show little or no counterrolling under any circumstances Normal subjects show no counterrolling of the eyes with tilt of the body when they are in a zero gravity trajectory (Miller et al , 1966) At zero gravity the relatively high specific gravity of the otoconia is of no consequence for stimulation of the hair cells embedded in the macular substrate Change in the orientation of the body is not accompanied by an change in a linear acceleration vector

It is appropriate to assume that the

threshold angle of the otolith organs for tilt will vary with the magnitude of the prevailing gravitational acceleration force A functional relation between counterrolling in minutes of arc, and degrees of tilt at each of three levels of acceleration is illustrated in Figure 8 46 for both normal subjects and labyrinthine defective subjects (Miller and Graybiel, 1965) With increase in the gravitational force above the normal gravitational force at the earth's surface, there is an increase in counterrolling of the eyes directly proportional to the increased acceleration force up to 2 25 $\times$ g, the maximum studied, and probably beyond (Woellner and Graybiel, 1959) Graybiel and his colleagues, using a photographic superimposition technique, have been able to measure counterrolling to an accuracy of 5 min of arc

TEMPORAL DURATION OF EFFECTS OF VESTIBULAR STIMULATION

When a subject is exposed to constant angular acceleration about a given axis, a sensation of rotation is induced along with nystagmus movements of the eyes There appears to be an increase in the perceived angular velocity for approximately 30 sec followed by an impression of gradual decrease in angular velocity There is no decline in the nystagmus response to sustained angular acceleration which correlates with this subjective impression (Guedry, 1965) Thus, the attractive notion that the appearance of rotation of the visual world is somehow directly correlated with nystagmus movements of the eyes is probably in error Experiments have shown that the impression of rotation of the visual world may occur when there is no nystagmus detectable and that some nystagmus may be detectable when a subject is unaware of any subjective impression of rotation (Gray, 1960)

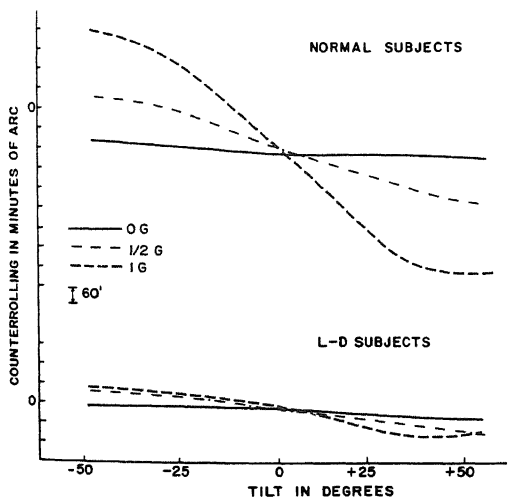

Fig 8 46 Mean counterrolling response of the eyes measured in minutes of arc as a result of tilting in angular degrees with respect to a resultant G-force Results are presented for both normal and labyrinthine defective (L-D) subjects (Miller and Graybiel 1965)

The effects of stimulation of the vestibular mechanism by angular acceleration may be measured in terms either of the impression of rotation, the so-called oculogyral illusion, or in terms of the measurable nystagmus movements of the eyes As suggested above, somewhat different results are obtained for these different indices Continuation of a nystagmus response with continuation of angular acceleration and reduction of the oculogyral illustion before termination of angular acceleration suggests that central factors may override the output of the peripheral sensing device as this influences conscious perception

For the usual exposures to angular acceleration for relatively short durations followed by the maintenance of a constant angular velocity for varying amounts of time, the perception of rotation and nystagmus both continue for 20 or 30 sec after angular acceleration has stopped in a normal subject This observation fits with the notion of the cupula as a damped torsion pendulum which gradually resumes its normal undeflected position when angular velocity is constant On the other hand, if rotation occurs about a horizontal axis, the perception of rotation continues for the entire duration of rotation even at constant angular velocity (Benson and Bodin, 1966) The explanation of this difference would seem to depend upon the fact that with rotation about a horizontal axis there is a continuously changing pattern of stimulation of the otolith organs This provides a continuing sensory input which corresponds to the continuing rotation even though the velocity is constant A curious aspect of this situation is that with rotation about a horizontal axis there is an immediate cessation of the impression of rotation when physical rotation is stopped In other words, although the semicircular canal stimulation resulting from deceleration should produce a continuing signal for some seconds after rotation is stopped, the perception of rotation stops immediately

Adaptation. As Adrian has pointed out (1943), the vestibular mechanism is not ideally suited to situations in which one is subjected to protracted angular motions Prior to the advent of high speed vehicles, particularly aircraft which can maneuver relatively freely in three-dimensional space, man was not ordinarily subjected to prolonged angular rotation The vestibular system may be ideally suited to coordination of the movements of the body and fixation of the eyes for short-term relatively low amplitude rotations, but this is clearly not the case for prolonged rotation After prolonged rotation at constant angular velocity, any deceleration results in sensory signals from the canals which are appropriate to rotations in the opposite direction and quite inappropriate to the actual motions involved This gives rise to difficulty of interpretation of the nature of the motion path of an aircraft in flight and has been blamed for innumerable aircraft accidents

The zero gravity environment of space is inconvenient from the standpoint of manipulating liquid foods and other aspects of daily living, and also presents certain physiological hazards with respect to venous return of blood to the heart and calcium metabolism For these reasons, it has been suggested that an artificial gravity might be useful for space stations and for space travel Such an artificial gravity could be achieved only by the maintenance of a constant angular velocity of the space station with occupants living at an appropriate radius so that the centrifugal force would provide an artificial gravity Problems arise by reason of the fact that the radius must necessarily be relatively short In moving about in such an environment, individuals will tilt their heads about various axes which may be orthogonal to the axis of rotation Such rotations give rise to Coriolis accelerations in which there may be a bilateral asymmetry of stimulation of the vestibular mechanisms The results of this effect can be most disturbing with respect to orientation and at worst may cause motion sickness

Investigations have been conducted in which volunteer subjects have lived in rotating environments on the earth's surface with the rotation about a vertical axis Free movement within such an environment is most disturbing and induces motion sickness in many subjects Adaptation to such an environment such that the effects of movement are no longer disturbing can occur if the rate of rotation is less than 6 or 7 r p m (Newsom et al , 1966) For rates of rotation above 10 r p m long-term adaptation is impossible (Graybiel, Clark, and Zarriello, 1960) Such a situation may actually be more disturbing than the situation which would exist in a rotating space station On the surface of the earth the major component of linear acceleration is the earth's gravitational component and a linear acceleration resulting from rotation is relatively small and constantly changing with movement of the individual along the radius of rotation

There appears to be little adaptation effect for the otolith organs when these are tilted to new positions in the earth's gravitational field Whereas the semicircular canals are stimulated only by angular acceleration and hence do not respond to constant angular velocity, the otolith organs are stimulated by the pattern of depression of the macular substrate by the otoconia Neural response, as described in greater detail below, continues relatively undiminished for each new position in which the head is placed If an observer is seated at a given radius on a centrifuge, rotating about a vertical axis, the otolith organs will respond to the resultant force of the centrifugal acceleration and the earth's gravitational field The result of this kind of stimulation is an impression of tilting of the visual world It is reoriented to conform to the direction of the resultant gravitational force as a new vertical reference This is known as the oculogravic illusion (Clark, 1967) On a centrifuge, the extent of tilt perceived by a subject is essentially constant for sustained acceleration at a constant angular velocity (Correra, Hixson, and Niven, 1968)

Habituation. The term, *habituation* is used as distinct from adaptation The former refers to effects of repeated exposure to angular rotation or accelerations Adaptation refers to effects which occur in a prolonged single exposure. It is well known that certain forms of habituation occur (Guedry, 1965) Tumblers and divers maintain a sense of their position in space while performing elaborate rotational movements which would be completely disorienting to anyone lacking in experience, if he could possibly perform the motions in the first place Figure skaters are capable of high speed rotation, as high as 280 r.p m for some sec-

onds, following which they can immediately go into another complicated skating routine or stand immobile They are able to suppress nystagmus motions of the eyes almost completely if they have an opportunity to look at their visual surroundings (Collins, 1966) Nystagmus movements have been detected by telemetry techniques in skaters, however, while they are in motion and after rotation if their eyes are closed It has also been demonstrated fairly conclusively that habituation is highly selective (Guedry, 1965) That is, a figure skater may be able to maintain complete control for rotation in a given direction with the head in an accustomed orientation On the other hand, if direction of rotation is reversed or if the head is tilted into an unusual posture, the result may be severe disorientation of the skater following the rotation

NYSTAGMUS

Nystagmus movements of the eyes usually associated with high angular acceleration consist of relatively slow components in the direction opposite to that of the acceleration and fast components in the direction of acceleration (Fig 8 47) Were it not extreme, the slow component would permit the maintenance of fixation on a point in the visual world in spite

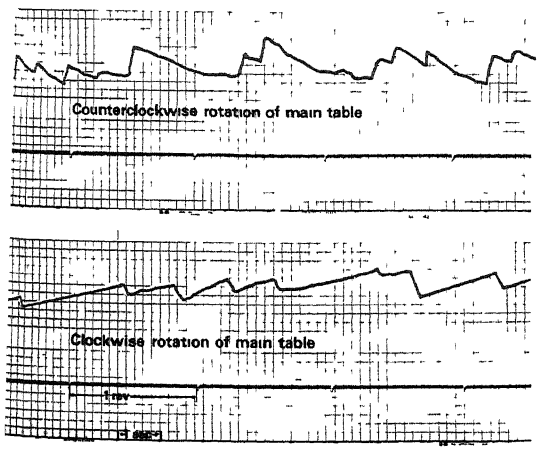

Fig 8 47 Records of horizontal nystagmus movements of the eyes of a cat to the right in the upper record and to the left in the bottom record These records appear typical of a nystagmus response to angular acceleration although they were obtained from an animal which was rotated on a small table located near the edge of a larger rotating table such that there was no resultant angular acceleration of the animal The experiment is described in the text (Money 1966)

of rotation Figure 8 48 illustrates the average slow phase nystagmus responses of 10 men subjected to an angular acceleration of 4°/sec ^{2} for a period of 45 sec (Crampton, 1965) It is evident that the direction of the slow phase is dependent upon the direction of rotation In addition, it is clear that the nystagmus effect continues for some 20 sec or more after the angular acceleration has stopped Cessation of the nystagmus in the initial direction is followed by a secondary nystagmus with the slow phase in the opposite direction The records in Figure 8 48 show some very slight evidence of *habituation* Average responses for the initial trials in each direction may be compared with average responses for the final trials in each direction The fact that the final trials show slightly lower maximum values is evidence of *habituation* This effect is even more marked with respect to the rate of reduction of nystagmus following termination of acceleration and the amplitude of the secondary nystagmus

There is also a suggestion of adaptation in the data presented in Figure 8 48 It appears that there may be a slight reduction in the nystagmus rate prior to the termination of acceleration The variability of the results is such that they cannot be interpreted as a clear-cut demonstration of adaptation, however As a matter of fact, nystagmus records, although they may show habituation, rarely show much if any adaptation Similar data for the same kind of exposure are presented in Figure 8 49 for the cat Here there is a much clearer demonstration of habituation, it is also somewhat clearer that there is no adaptation

For clinical tests using a rotating chair, a usual procedure is to rotate the subject at a rate of once every 2 sec for a total of 10 revolutions The chair is then stopped abruptly Nystagmus motions are observed which have been induced by the abrupt deceleration of the chair The slow phase is thus in the same direction as the original direction of chair rotation If, during rotation the head is nearly erect but tilted forward approximately 30°, then the nystagmus movement of the eyes will be from side to side or horizontal If the head is tilted down nearly 90° onto one shoulder with rotation about a vertical axis, then the direction of nystagmus will be up and down with respect to the head If the head is tilted back 60° or down 120° from the erect position,

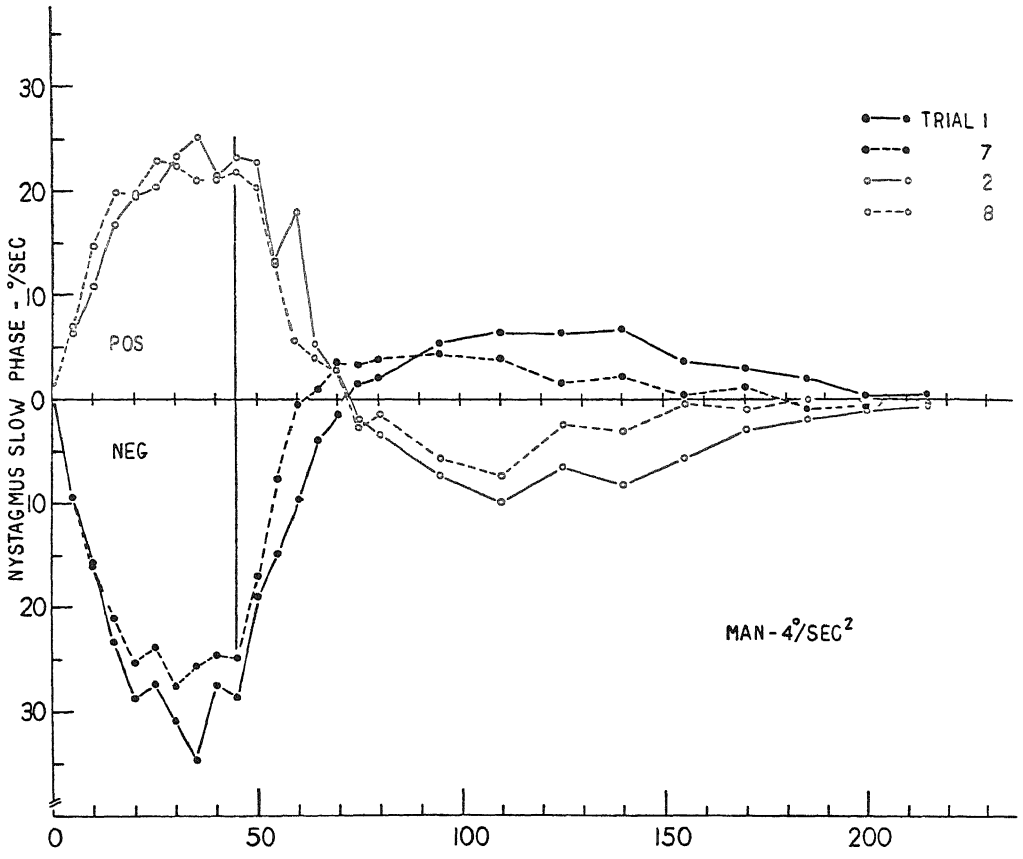

Fig 8 48 A record of the velocity of the slow-phase of horizontal nystagmus in man during and following exposure to angular acceleration at the rate of 4°/sec ² The termination of acceleration at approximately 45 sec is marked by a vertical line on the graph Results are the average responses for 10 men Results represented by solid circles are for counterclockwise or negative acceleration and results represented by open circles are for clockwise or positive accel eration The first trial for acceleration in a given direction is represented by a solid line the last trial by a dashed line The reversal of direction of nystagmus the so-called secondary nystagmus is shown in all of these records where they cross the zero point on the ordinate axis (Crampton 1965)

then the nystagmus will be rotary That is, rather than a linear motion there will be a torsional movement of the eyes This is slightly more difficult to observe but can readily be detected by referring to some unique characteristic of the iris or a vessel within the sclera A wide variety of nystagmus motions is possible dependent upon the position of the head with respect to the axis of rotation It is evident that the three pairs of semicircular canals work in concert to drive the appropriate extraocular muscles for compensation of motion of the head about any axis of rotation

Nystagmus may also be induced by the movement of objects in a given direction before the eyes. Thus, if the eyes are open during rotation, the *optokinetic* nystagmus will be in the same direction as the vestibular nystagmus and they will serve to enhance each other With the eyes open during deceleration, optokinetic nystagmus will tend to cancel out the vestibular nystagmus For this reason, in observing nystagmus effects with the rotating Barany chair, subjects are instructed to keep their eyes closed until the rotation of the chair has been stopped, at which point the eyes are opened for observation.

It is the slow phase of nystagmus which is initiated by the semicircular canals The quick component, which is merely a kind of "reset" motion, is attributed to unknown central pathways The characteristics of the slow phase provide us information as to vestibular response to stimulation

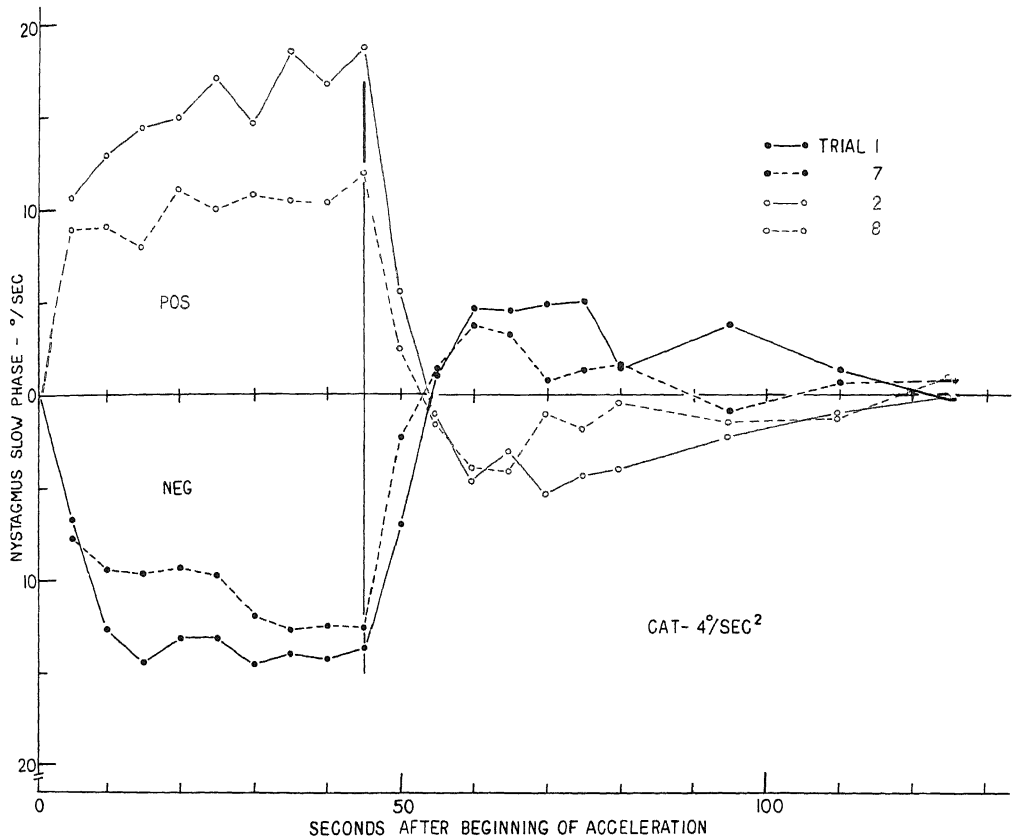

Fig 8 49 Results similar to those presented in Figure 8 48 representing average values for 10 cats the stimulus series was identical to that upon which the preceding figure was based (Crampton 1965)

Nystagmus has been observed in the absence of any angular acceleration of the semicircular canals If a small rotating table is located at the end of an arm which is rotating at the same angular rate but in the opposite direction, both about vertical axes, an animal on the table will maintain a constant geographic heading Under these circumstances nystagmus has been observed in man and in cats (Fig 8 47) The stimulus is a rotating linear acceleration vector which does not cause rotation of liquid in a closed vessel such as the semicircular canals Some action on the otolith organs might be inferred, but cats with defective otolith function also show the effect (Money, 1966) Nystagmus may result from effects of changing direction of linear acceleration on tissues of differing density within the ampullae of the canals

Orienting Responses. The vestibular stimulation which results in nystagmus movements of the eyes influences other musculature as well In a number of animals, nystagmus movements of the whole head may be observed Whole body orientation in the direction opposite to that of rotation may also occur There is a tendency for increased tone in the extensors on the side of the body in the direction of rotation and increased tone in the flexors on the side away from the direction of rotation The direction of these effects is, of course, reversed following deceleration Thus, if a subject is instructed to stand up and walk as soon as the rotation of the Bárány chair is stopped, he will tend to stagger or fall in the direction of the rotation

Electrophysiological Responses to Vestibular Stimulation

Electrical activity from single cells of the vestibular system has been a subject of study for a number of years (Ross, 1936, Lowenstein and Sand, 1936, Adrian, 1943)

SEMICIRCULAR CANALS

Gernandt (1949) reported on responses from three different classes of cells which he designated types I, II, and III The first of these responded by increased spike discharge with rotations in a direction which would cause bending of the cupula of the lateral canal in the direction of the utricle Rotation in the opposite direction resulted in an inhibition of the resting level of response of the unit The second type of cell responded with an increase in firing rate with acceleration in either direction The third type showed a decrease in firing rate with acceleration in either direction Gernandt had made these observations in the cat The first two types of cell were also found by Eckel (1954) and all three were reported by Duensing and Schaefer in 1958 The latter investigators also reported a new type of response, one in which the firing frequency of the unit was increased by rotation in a direction which would result in bending of the cupula of the horizontal canal away from the utricle and decreased for rotation in the opposite direction The response of this type was thus just the opposite of the first type of unit reported by Gernandt The first type may be thought of as conforming with predictions which one might make from the second law of Ewald concerning the appropriate direction of stimulation for the horizontal canals

There are a number of procedural factors which must be considered carefully in stimulating the vestibular system If the axis of rotation does not pass through the vestibular mechanism from which the recorded responses originate, then there will be a linear component of acceleration force imposed on the mechanism in addition to the angular acceleration This might result in stimulation of the otolith organs and the generation of responses which could be mistakenly attributed to semicircular canal function Another problem relates to the difficulty of so orienting the preparation that only one pair of canals is stimulated With the head erect, the lateral canals are stimulated most effectively, but there is some component of stimulation of the vertical canals as well This may be minimized or eliminated by inclination of the head forward by approximately 30°

Crampton (1965) has reported studies of single unit responses from the brain stem of the cat in which great care was taken to control the orientation of the head of the animal with respect to the axis of rotation In addition, precise control of the rate of angular acceleration was possible and the device permitted a smooth transition from rotation in one direction through 0 angular velocity to rotation in the other direction He found the type I cells of Gernandt which responded in accordance with Ewald's principle for lateral canal stimulation as well as the type of cell with an opposite response which had earlier seen reported by Duensing and Schaefer (1958) He did not find any cells which responded always with increase in firing rate or always with decrease in firing rate for either direction of angular acceleration He attributed the earlier reports of responses of this kind to possible slight displacement of the otolith organs from the axis of rotation The "non-Ewaldian" type of response was attributed by Crampton to a component of stimulation which influenced the vertical canals With the head erect, a direction of angular acceleration which would cause bending of the cupula in the horizontal canal in the direction of the utricle would also cause bending of the cupulae of the two vertical canals in the same direction However, as Ewald pointed out, the appropriate direction of the bending of the cupulae of the vertical canals for excitation is utriculofugal Therefore, these canals would provide an opposite effect as compared with the horizontal canals With the heads of his animals tilted downward 30° with respect to the stereotaxic horizontal plane, Crampton was unable to find any "non-Ewaldian" units With the head erect, they were found even when the contralateral branch of the eighth nerve had been sectioned, supporting his contention that they reflect ipsilateral effects in the vertical canals

Two different patterns of response were found in the cells studied by Crampton With positive acceleration there is a slight delay of the response which then builds up to a maximum value with approximately 45 sec of the beginning of angular acceleration With cessation of angular acceleration the response decays exponentially over a period of 50 sec or more Acceleration in the opposite direction results in suppression of response Approximately 20 sec after stimulation some activity reappears, but this then subsides below the normal resting level after about 100 sec and remains suppressed for over 5 min

Cells of the other sort respond with increase

in spike discharge frequency for angular acceleration in one direction and decrease in spike discharge frequency for angular acceleration in the other direction, but their level of activity does not return to a resting level with the cessation of angular acceleration The level of activity remains in the state induced by the angular acceleration for more than 5 min after acceleration exposure The level of activity may be "switched" to the lower or higher level, depending on its state, by accelerating the animal in the opposite direction These units thus appear to "remember" the direction of the last angular acceleration for a sustained interval after acceleration has stopped

OTOLITH ORGAN RESPONSE

Electrical activity of the otolith organs has been studied primarily in the fish by Lowenstein and his associates Recording directly from the otolith organs of the skate, Lowenstein and Roberts (1949) discovered several distinct types of receptor response patterns The stimulus consisted of tilting of the preparation in the earth's gravitational field In Figure 8 50, discharge frequencies are shown for a receptor in the utricle of the ray for each of a series of orientations of the animal through 360° of rotation The data were redetermined at each point with repositioning of the animal in the opposite direction Rate of change of position was not a matter of concern Recordings were made after the response had stabilized for a given position The unit which is represented in Figure 8 50 appears to be a position-sensing unit which provides a response frequency characteristic of a fixed orientation in space There is clearly some ambiguity in the response of such a unit, however Pairs of positions may be selected for which the impulse discharge frequency is the same, although the positions are quite different Other units have been found in the ray which respond maximally for a specific position such as upright, (Fig 8 51) and others have been found for which response frequency in a given position varies with the direction of rotation from which that position was achieved (Fig 8 52) Other receptors have been found which are obviously dependent upon rate of change of position for their response characteristics as well as position itself The combined function of all of these different receptor types would appear to provide a rich background of sensory input for the discrimination of the posture of the head in space as this changes in time

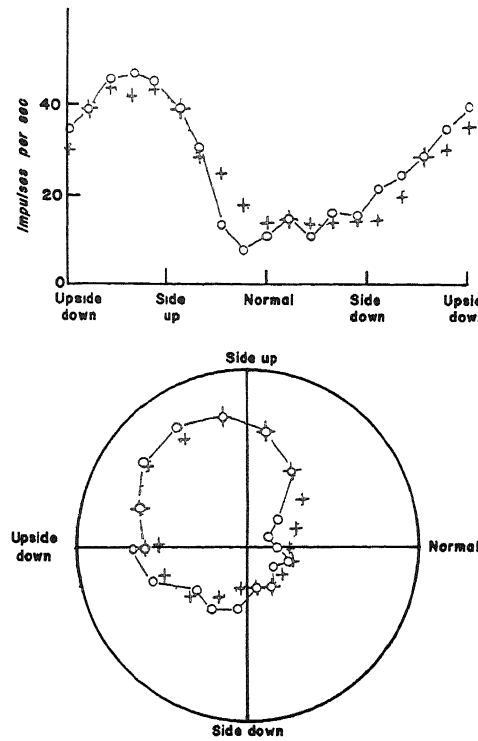

Fig 8 50 Rectilinear and polar plots of the firing frequency of a position receptor in the utricle of the ray as a function of skull position for full 360° rotation of the animal The continuous line represents clockwise rotation the dotted line represents counterclockwise rotation (Roberts 1967)

MOTION SICKNESS

The sensation of spinning of the visual world following rotation has been termed the oculogyral illusion This may not be an unpleasant experience and has been extremely useful as an index of the course of effects of vestibular stimulation The sensation of a whirling environment is also called vertigo It refers to the same phenomenon as the oculogyral illusion that is usually applied in extra experimental settings or under circumstances where the sensed rotations are disturbing The general feeling of *dizziness* may or may not include vertigo and is associated with unsteadiness and disequilibrium Vertigo may be a serious problem for the pilot of an aircraft if it results in confusion on his part with respect to his position or movement in space It is also serious as a concomitant of motion sickness

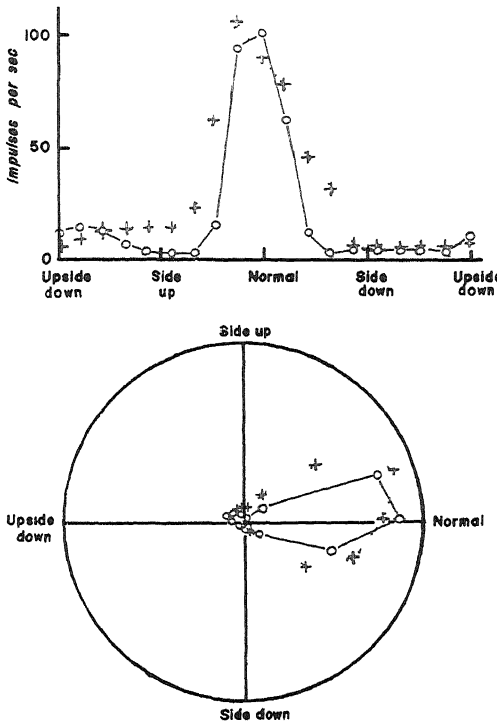

Fig 8 51 Rectilinear and polar plots of firing frequency as a function of skull position for a unit in the lagena of the ray which appears to respond only for positions in the vicinity of the normal upright position (Roberts 1967)

Unusual motion patterns in which the head is rotated about 2 axes simultaneously can produce motion sickness in anyone Some individuals are more resistant than others, but none is immune Motion sickness may also occur when visual and vestibular stimuli are not in accord Such a situation occurs for someone on board ship who is unable to see the stable horizon His visual environment moves with him and does not behave as would a stable visual world for the patterns of motion to which he is exposed by the pitching and rolling of the ship Motion sickness may also be induced when the body is perfectly stationary but the visual world, as seen in a motion picture film for example, changes as it might during airplane acrobatics or a roller coaster ride An important element in the induction of motion sickness is apparently lack of accord between visual and vestibular inputs The symptoms of motion sickness are similar to the effects of alcoholic intoxication An important component of each is the reaction of the autonomic nervous system This is immediately associated with the feeling of nausea, vomiting, and pallor Blood pressure may be lowered by as much as 10 mm of Hg and heart rate may be reduced by 8 or 10 beats/min

The nature of the motions encountered on shipboard are such that the cause of motion sickness has long been attributed primarily to otolith function (Sjoberg, 1968) The dominant role of the otoliths, however, has been seriously questioned (Graybiel and Miller, 1968) Since the discovery that the semicircular canals may respond to linear acceleration, particularly to change in the orientation of a linear acceleration vector (Miller and Graybiel, 1968), a more significant role has been attributed to the canals As mentioned above, motion sickness may be induced in the absence of any actual

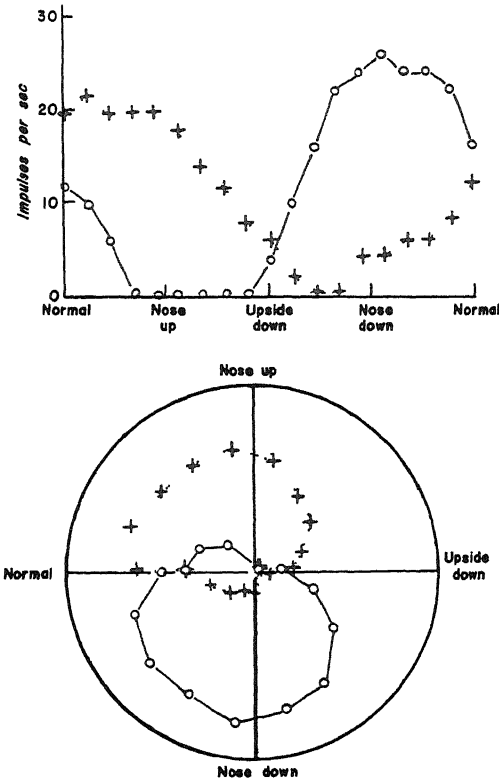

Fig 8 52 Rectilinear and polar plots of impulse frequency of a receptor in the utricle of the ray as a function of skull position during two 360° rotations in opposite directions It is evident that the response of the unit is influenced by direction of rotation Continuous curves represent clockwise rotation dotted curves represent counterclockwise rotation (Roberts 1967)

motion if visual stimulation depicting motion is presented (Miller and Goodson, 1961, Crampton and Young, 1953) Such visual motion stimulation is not effective in the induction of motion sickness in the absence of a functioning vestibular mechanism, however, (Crampton and Young, 1953) When visual inputs provide information that correlates with vestibular stimulation, vision may serve to reduce the incidence of motion sickness (Johnson and Taylor, 1961)

Inappropriate vestibular responses may occur following ingestion of alcohol, giving rise to the vertigo and dizziness experienced Alcohol does not increase nystagmus in the dark, however Increased nystagmus in the light following ingestion of alcohol is probably a result of the interference by alcohol with the normal visual suppression of nystagmus responses Nystagmus which occurs when the head is placed in certain positions after the ingestion of alcohol may be detectable for many hours after ingestion and after the level of alcohol in the blood has dropped to the normal range (Aschan, 1958)

An extensive survey of the effectiveness of a variety of drugs in combating motion sickness (Wood, 1968) strongly suggests that the effectiveness of such drugs is based on their action on the autonomic nervous system Both drugs which block parasympathetic activity and drugs which stimulate sympathetic activity are effective Scopolamine appears to be the most effective single drug The commonly used antihistamines are less effective and useful only in prevention of motion sickness under conditions of relatively "mild" stimulation

Labyrinthine Dysfunction

Any abrupt interference with the normal function of the labyrinth organs, particularly the vestibular mechanism, may be accompanied by the disturbing subjective symptoms of vertigo and dizziness along with ataxia and gross impairments of coordination A variety of conditions may be classified as labyrinthitis, accompanied by vertigo and the other symptoms referred to Inflammation of the vestibular branch of the eighth nerve, local infection within the vestibular mechanism and abnormal fluid balance within the system may be responsible for disturbances Treatment of such conditions is usually symptomatic Drugs which are effective in the prevention of motion sickness may be useful (see above)

Gross vestibular impairment accompanied by paroxysmal attacks of vertigo, subjective noise (tinnitus aurium) and a progressive impairment of hearing of the sensorineural type characterize a syndrome which is known as Meniere's disease Involvement of both vestibular function and the hearing mechanism suggests a localization of the disease process within the labyrinth It is generally attributed to disturbed fluid balance within the inner ear and distention of the cochlear duct has been observed upon postmortem examination of patients who had suffered from the disease Symptoms may be relieved by reducing the sodium intake Intractable cases have been treated by surgical destruction of the labyrinth, intracranial section of the vestibular division of the eighth nerve, or ultrasonic irradiation of the vestibular end organs for their destruction Labyrinthotomy performed under these circumstances has grossly different effects than those observed in animals The reason is probably that gross disturbance of the mechanism already exists before such intervention is carried out in man In a normal animal, destruction of the labyrinthine mechanism unilaterally has a result similar to excitation of the contralateral vestibular system Slow nystagmus movements are observed in the direction of the damaged side, there is a tendency for increased tonus of extensors on the undamaged side and of flexors on the damaged side

Vestibular function may be impaired by the administration of specific toxic substances such as streptomycin In doses of 2 g or more daily over a period of weeks, the occurrence of vestibular symptoms is fairly frequent Animal studies suggest a direct action on the peripheral sense receptors, although it has been suggested that in man the effect may be on the ventral cochlear nuclei The effects of streptomycin ingestion are usually bilateral If medication is stopped sufficiently early, the effects may be reversible Vestibular function is impaired before there is gross evidence of hearing loss Hearing impairments are greater for frequencies of 4000 Hz and above so that the deficit may not be noticed as these frequencies are of relatively little importance for the perception of speech

Diagnosis of vestibular impairment is accomplished by artificial stimulation of the vestibular mechanism. This may be accomplished by rotation in a chair or by caloric stimulation. Following rotation of the head about various axes, nystagmus movements of the eyes are timed and their duration is compared with normal standards. Impaired function is frequently associated with a greatly reduced duration of nystagmus. Similar observations are made following caloric stimulation. Caloric stimulation has the advantage of permitting selective unilateral stimulation. The selection of canals to be stimulated may be controlled to a limited extent by positioning of the head during stimulation. The effect of stimulation is believed to be based on convection currents so that the one canal which can be located in a horizontal plane will not receive stimulation.

LIGHT AND THE OPTICS OF THE EYE

Introduction · Light

Within the entire range of frequencies of electromagnetic radiation (70 octaves) only a narrow band of frequencies is effective in the stimulation of the eye It represents a range of only one octave, and in terms of wavelength extends from approximately 370 to 740 nm (10^{-9} meters) The distribution of frequencies and wavelengths of electromagnetic radiation is illustrated in Figure 8 53 Light is on the same continuum with γ rays, x-rays, and broadcast bands of radiation

The velocity of light in a vacuum is a universal constant It is the same for all frequencies When light enters any physical medium, however, its velocity is reduced The amount of reduction depends on the nature of the medium and the frequency of the light The ratio of the velocity of light in a vacuum to its velocity in a given medium defines the refractive index, n, of the medium The value of n for air is very nearly unity The higher the frequency, the larger is the value of n for a given medium The frequency of propagation remains constant independent of the medium through which light is transmitted and hence, as velocity is reduced, wavelength must also be shortened by a proportional amount

By application of the wave theory of transmission of electromagnetic energy, it can be demonstrated that light which passes from one medium into another will have its direction of propagation altered if it enters the new medium along a path which is other than perpendicular to the interface between the two media The ratio of the sine of the angle formed between the path of the light in the less dense medium and a perpendicular to the surface between the media to the sine of the angle formed by the path in the more dense medium with respect to the same perpendicular is equal to the index of refraction for the two media (Fig 8 54)

The principle of refraction is extremely important in a variety of ways If the surface between two media is not a plane but is curved, then rays of light which reach this surface at different points in a beam of large cross-section will be refracted by different amounts and will be propagated through the new medium in different directions It is on the basis of this principle that lenses may be formed from glass These can cause parallel beams of light to converge or diverge depending upon the design of the lens (Fig 8 55) Light of shorter wavelength is refracted a greater amount than light of longer wavelength Thus, a beam of white light which consists of a continuous distribution of energy for all visible frequencies from the longest to the shortest will be spread out if it enters glass at an angle other than perpendicular and the components of different frequencies will travel along different pathways This principle is turned to practical advantage by the use of the prism which permits the separation of the spectral components of light (Fig 8 56)

Although light is often specified in terms of its wavelength, it is more sensible to specify it in terms of frequency The reason for this is that the frequency of light is not altered when it passes from one medium into another of different refractive index Velocity does change and thus wavelength must also change a proportional amount For this reason, light is sometimes described in terms of its *wave number*, the reciprocal of wavelength in centimeters, which is directly proportional to frequency There are additional advantages in describing light in terms of its frequency or wave number associated with the characteristic form of the absorption spectra of certain pigments

QUANTUM THEORY OF LIGHT

Certain physical phenomena can only be understood in terms of the notion that light energy consists of a number of individual particles, each of which represents an indivisible,

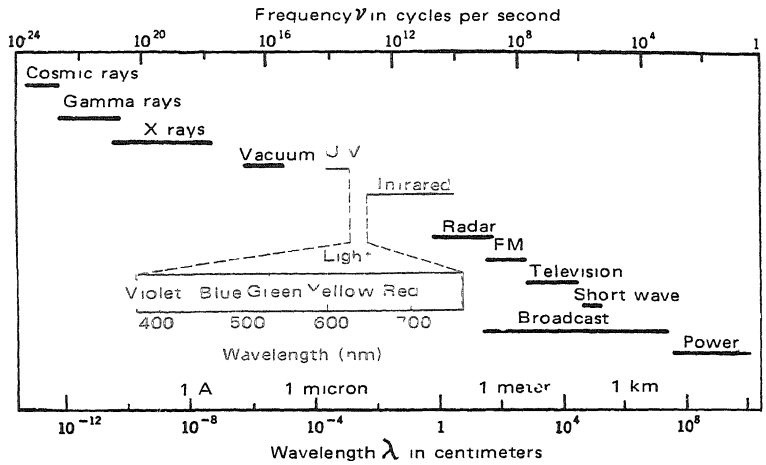

Fig 8 53 The electromagnetic radiation spectrum The region visible to the human eye is expanded (From McKinley 1947)

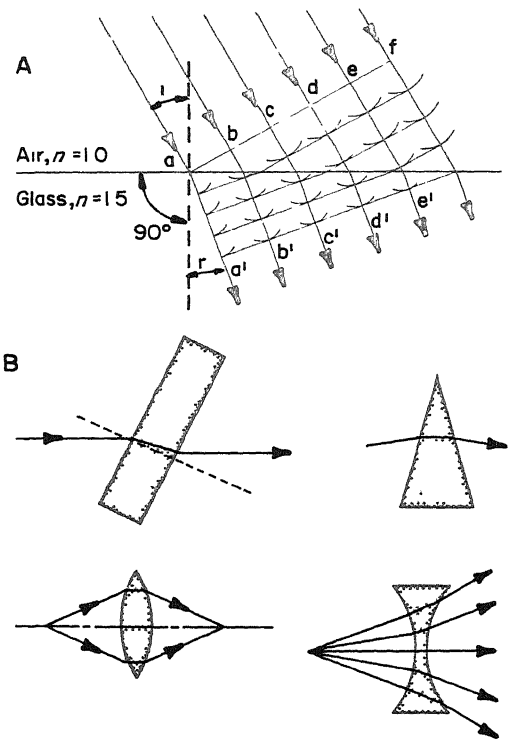

Fig 8 54 *A* refraction of light at a surface between glass and air Angle *i* is the angle of incidence and angle *r* is the angle of refraction Index of refraction *n* is given for each medium The rotation of wave front abcdef as it enters a medium of higher index of refraction at an angle other than normal to the interface is shown by wave front a'b'c'd'e'f' *B* deviations in the path of light as it is passed through glass of various geometric forms plain glass a prism a convex lens and a concave lens (Riggs 1965a)

minimum energy unit These are called *quanta* for the entire electromagnetic spectrum They are sometimes called *photons* for energy within the visible range The energy of a single quantum or photon of light is proportional to its frequency For a given frequency, the energy thus remains constant with changes in velocity as it passes through different media Energy may be computed from the following relation

$$E = h \times \nu$$

where E is the energy in ergs, h is Planck's

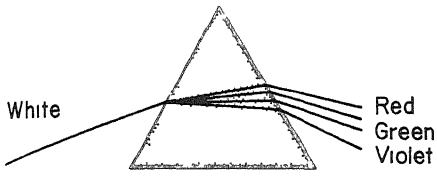

Fig 8 56 Dispersion of light by a prism

Constant, 6 6245 × 10^{-27} erg-sec and ν is frequency

THE MEASUREMENT OF LIGHT

Because only a narrow band of electromagnetic radiation is effective as a stimulus for vision, the measurement of light must take into account, not just the radiant emission of a light source independent of its wavelength, but also the effectiveness of the radiant energy as a stimulus to the eye Radiation of a continuously emitting source is measured in terms of energy per unit time For a point source, the measurement may be expressed in terms of the energy per unit time which irradiates a fixed area at a given distance from the source The fixed area at a given distance defines a solid angle and the radiation may thus be expressed in terms of ergs per second, or watts, per unit solid angle The rate of emission from the source is thus defined in terms which permit the computation of the amount of energy per unit time that will fall on any given surface at any given distance from the source The measure is one of the *intensity* of the source

If the source is extended rather than a point source, its emission must be expressed in terms of radiant energy per unit area Here, however, the orientation of the emitting surface with respect to the receiver or viewer becomes important This is taken into account by considering the area of the source projected on a plane normal to the axis along which observations are made The emission from an extended surface is termed its radiance and is expressed in terms of watts per unit solid angle per meter^2

Photometric Units. Even in the range of wavelengths to which the eye responds, the response is not uniform It depends upon the selective transmittance of the various optical elements of the eye itself and most importantly, on the absorption characteristics of the photopigments of the visual receptors Careful measurements have permitted the specification of a *spectral luminosity function* for human vision, V_λ (Fig 8 57) It is important to consider some of the limitations of this function In the first place, it represents the spectral response of the eye at "daylight" levels of illumination The spectral response of the eye changes at very low levels of illumination to the function represented by V'_λ These curves are average curves for a large number of observers and are based on the effectiveness of light as measured by a specific criterion The more effective a wavelength as a stimulus to the eye, the lower will be the radiant flux required for fusion of light flickering at a given frequency

The curves in Figure 8 57 are based on the reciprocals of radiant flux or energy requirements and have arbitrarily been set equal to unity at the wavelength of minimum energy requirement The low luminance V'_λ function actually represents a higher absolute level of sensitivity than the V_λ function

Unfortunately, the relation between the effectiveness of light energy based on criteria such as matching a standard or the apparent fusion of a flickering source is not perfectly correlated with the effectiveness of light energy for such tasks as reading and a variety of

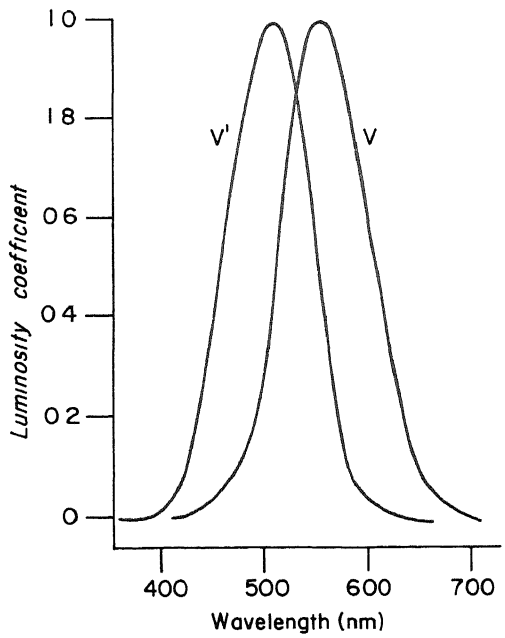

Fig 8 57 The scotopic (V') and photopic (V) curves of relative spectral luminosity as standardized by the Commission Internationale de L Eclairage (C I E) (From Wright 1958)

other visual functions of a practical sort Nonetheless, it does provide a reasonable approximation The units of light are based upon the weighting of a measurement of radiant power in appropriate units in accordance with the luminosity function presented in Figure 8 57 The photometric dimensional equivalent of the watt is the lumen At the wavelength where radiant energy is most effective in stimulating the eye, approximately 555 nm , one watt is equivalent to 680 lumens according to the accepted standard which provides a basis for photometric specification Radiant power of any other wavelength is less effective in accordance with the ordinate values of Figure 8 57 There is a variety of useful sources of detailed information on the specification of light for the interested student (Riggs, 1965a, LeGrand, 1968)

Optical Properties of the Eye

Prior to reaching the photosensitive layer of the retina, light which stimulates the eye must pass through the cornea, the anterior chamber, the vitreous humor, and a number of nonsensitive retinal layers (Fig 8,58) The distance from the corneal surface to the retina in the region of the foveal center of the eye is approximately 24 mm The optical elements of the eye must therefore provide a fairly high optical power in order to focus parallel rays which enter the eye at the retina The power of the eye is nearly 60 diopters Lens power is defined as the reciprocal of the focal length of the lens in meters The nodal point of the eye may be assumed to be approximately 17 mm in front of the retina and parallel rays may therefore be assumed to be brought to a point of focus in that distance The lens power of the eye is achieved primarily by the curvature of its corneal surface and secondarily by the power of the cystalline lens The refractive index of the cornea is 1 37, of the aqueous humor, 1 33, of the crystalline lens, 1 42, and of the vitreous body 1 33 Thus, maximum convergence of parallel rays occurs at the interface between the cornea with its refractive index of 1 37 and air with a refractive index 1 The radius of curvature of the cornea is nearly 8 mm at its anterior surface The refractive indices between the aqueous humor of the anterior chamber and the lens, and between the lens and the vitreous humor are sufficient to provide some additional positive power as a result of the convex shape of the lens The shape of the lens may be changed by the process of accommodation Contraction of circular fibers within the cilliary body relieves tension on the lens and its surface becomes more convex This permits an increase in the optical power of the eye by nearly 9 diopters Thus, accommodation is changed from a far point at infinity (for practical purposes 20 ft or more) to a near point of 10 or 11 cm

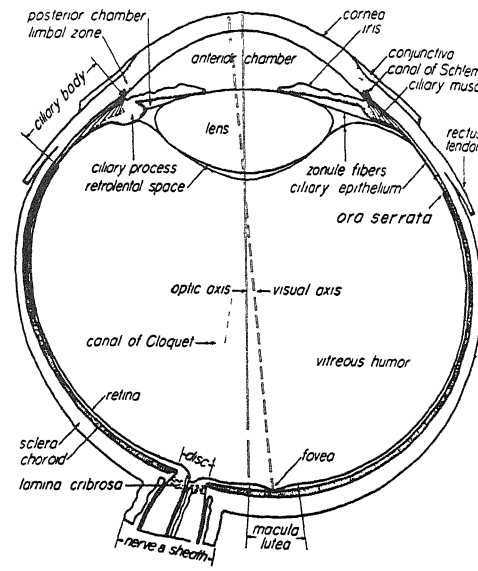

Fig 8 58 Horizontal section of the right human eye (From Walls 1942)

The intraocular media of the eye are not completely transparent The cornea begins to transmit light at wavelengths around 300 nm and its transmittance increases to a maximum in the region of approximately 1000 nm This is well beyond the practical limit for vision That limit is determined by the maximum wavelength which is absorbed by the photosensitive pigment of the retina Nonetheless, it is important to recognize that the cornea will transmit energy up to approximately 2000 nm , well into the infrared region The lens transmits energy over the same wavelength range but very little is transmitted at wavelengths longer than 1300 nm The aqueous humor absorbs virtually all energy at wavelengths longer than 2700 nm and the vitreous humor absorbs virtually all energy at wavelengths longer than 1600 nm The minimum wavelength effective in stimulating vision is of the order of 370 nm in the average adult

Shorter wavelengths may stimulate vision directly in the very young but there is a gradual yellowing of the ocular media with increasing age and accompanying attenuation of near ultraviolet energy down to 300 nm Between 350 and 400 nm , radiant energy may cause fluorescence of the lens As indicated, the fluorescent energy will be lower than the energy of the radiation which causes it and hence will be at longer wavelengths The appearance of light when the eye is stimulated by radiant energy at 350 nm may therefore result from longer wavelength fluorescence and cannot be interpreted to prove that the eye is capable of detecting energy at a wavelength of 350 nm

THE PUPIL

The total amount of light which may enter the eye is limited by the iris diaphragm or pupil This may vary in diameter from approximately 2 to 8 mm This four to one change in diameter corresponds to a 16 to 1 change in area and a commensurate change in the level of retinal illumination for a given level of illumination at the cornea A sphincter muscle innervated by the parasympathetic nervous system causes contraction of the pupil, a dilator muscle, innervated by the sympathetic nervous system causes dilation of the pupil Any abrupt increase in the level of illumination causes a pupillary reflex, observable in both eyes even though only one eye may be illuminated The diameter of the pupil is stopped down to a smaller size and then, if the illumination remains the same level, the pupil will open slightly to a steady state condition a little larger than the maximum initial constricted size Reduction in pupil size affords some protection for the eye at high levels of illumination, but this may not be its most important function

Almost any optical system suffers from certain imperfections Variation in the refractive index with the wavelength of light results in a different lens power for different wavelengths and therefore some distortion at the image for any illumination which represents a broad band of wavelengths In addition, the eye suffers from spherical aberration That is, rays of light which enter the lens near its periphery may be brought to a focus at a slightly different depth than other rays entering near the center of the lens These two types of aberration are illustrated in Figure 8 59 The smaller

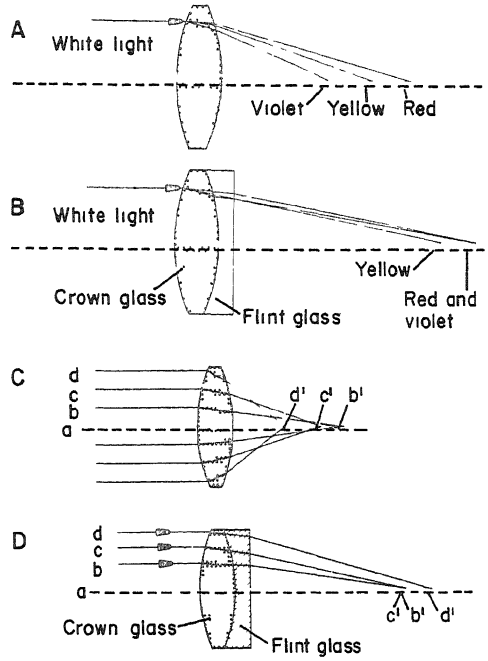

Fig 8 59 Chromatic and spherical aberration *a* chromatic aberration in a simple lens *b* achromatic lens partially correcting chromatic aberration *c* spherical aberration in a simple lens *d* achromatic lens partially correcting spherical aberration (Riggs 1965a)

the pupil of the eye, the less will be the degradation of the retinal image by reason of spherical aberration In addition, the greater will be the depth of focus of the eye as an optical system and hence the less will be the distortion due to chromatic aberration Therefore, the higher the level of illumination and, consequently, the smaller the pupil, the sharper will be the retinal image

The accommodative reflex, adjustment of lens size to decrease the focal length of the eye, is accompanied by pupillary constriction independent of any change in level of illumination The reduced pupil size increases depth of focus and thus provides a sharper retinal image when objects are viewed close to the eyes Unfortunately, there is a limit to the advantage which may be gained by pupillary constriction When light passes through a very small aperture, diffraction effects occur These may be viewed as interference and reinforcement effects such that the image of a point of light will consist of a central bright spot surrounded by a series of dark and light rings Thus, if the pupil is too small, diffraction effects will degrade the image An optimum

pupil diameter is probably between 2 and 3 mm For larger pupil diameters, spherical and chromatic aberration effects degrade the image, for smaller pupil diameters diffraction effects degrade the image

THE STILES-CRAWFORD EFFECT

Under normal conditions of daylight viewing, a specialized set of receptors, the cones, provide a basis for visual sensitivity Apparently, the geometry of these receptors and their orientation within the retina is such that they absorb light more efficiently the more nearly its point of entry into the eye is on the central visual axis of the eye Deviation of the point of entry away from the center by as much as 4 mm with the pupil at maximum diameter may reduce the effectiveness of light as a stimulus for the cones by a factor of 10 The relation of the luminous efficiency to eccentricity of the point of entry is illustrated in Figure 8 60 This indicates that the gain in retinal illumination in terms of actual effectiveness of stimulation of cones is not directly proportional to the increase in pupil area with dilation of the pupil No effect of this sort is found at low levels of illumination when the scotopic receptor system, dependent upon the rods, provides a basis for visual sensitivity Apparently the geometry and orientation of the rods are not as critical in determining their ability to absorb incident light

CHANGES IN THE LENS WITH AGING

It has been indicated above that the lens is capable of effecting a change in optical power of the eye of as much as 9 or 10 diopters Unfortunately, this does not remain the case indefinitely Almost from birth there is a gradual stiffening of the lens such that the range of change in curvature is gradually reduced with age Beginning at an age somewhere in the vicinity of 45 years, most people must begin to wear glasses for reading Their eyes are no longer capable of providing good accommodation for printed material at a comfortable reading distance If the material is moved sufficiently far away to provide for a sharp image on the retina, the size of the retinal image is too small for resolution of the letters The condition is easily rectified by the use of a positive lens in front of the eye

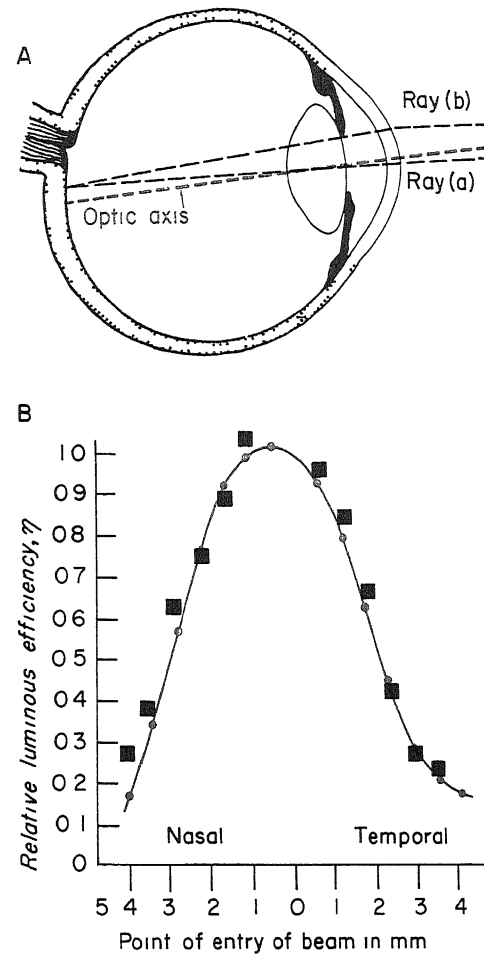

Fig 8 60 *A* the eye in horizontal section to show the Stiles-Crawford effect *B* the relative luminous efficiency of light entering the pupil at various points in a horizontal plane relative to the center of the eye Results for the left eye are indicated by squares for the right eye by dots (From Stiles and Crawford 1933)

OPTICAL DEFECTS

In a normal eye with relaxed accommodation, objects at an optical distance of infinity should be brought to focus on the retina Such an eye is said to be emmetropic If the point of focus is located out in front of the retina it is necessary to move the object toward the eye, displacing the image further to the rear of the optical elements of the eye, until it falls on the retina, in order to see it sharply Such an eye is said to be myopic If the image of an object at optical infinity falls behind the retina, then increased accommodation of the lens is neces-

sary in order to bring it forward onto the retinal surface Such an eye is said to by hypermetropic

Myopia is usually attributed to an elongation of the eyeball, although it may well involve abnormalities of curvature of the optical elements Conversely, hypermetropia is attributed to a foreshortening of the axial length of the eye ball It, too, may involve deviations from normal of the optical elements, however Myopia is correctible by the use of a negative or diverging lens in front of the eye in order to permit distance vision Frequently a myope without too severe a deficit may be able to read perfectly well without correction The hypermetrope will require a positive lens for reading, or, at least, will have to start wearing glasses at an earlier than normal age as his accommodative reserve is lost (Fig 8 61)

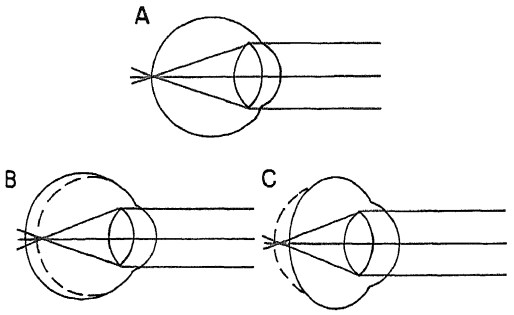

Fig 8 61 Comparison of shapes of the eyeball which may be associated with *A* emmetropia *B* myopia *C* hypermetropia

VARIATION IN THE SPATIAL RESOLUTION CAPABILITY OF THE EYE AS A FUNCTION OF THE LOCATION OF THE STIMULUS

Unlike a photographic film, the resolving power of the photosensitive layer of the eye, the retina, is not uniform over its entire surface A condition of optimum clarity is achieved for images which fall on or in the neighborhood of the visual center of the eye, the fovea (see Fig 8 58) The distribution of receptors over the retina is nonuniform with the greatest concentration of cones in the foveal center The concentration of rods increases from a point just outside the rod-free fovea to a maximum at a distance of some 20° from the foveal center (Fig 8 62) The distribution of receptor

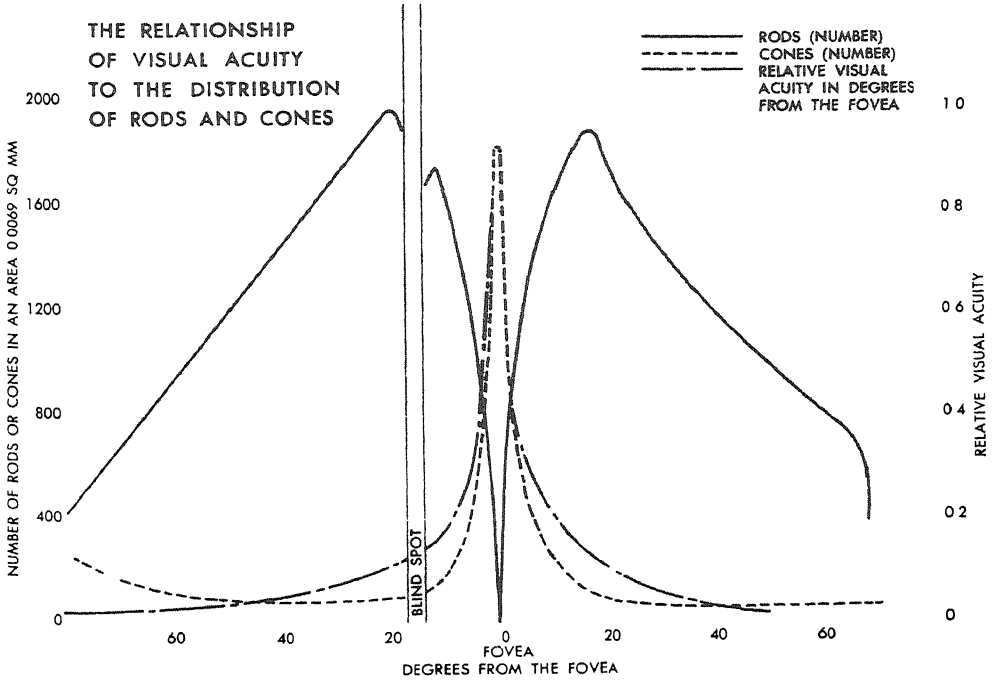

Fig 8 62 Distribution of rods and cones along a horizontal meridian Parallel vertical lines show the limits of the blind spot Visual acuity for a high luminance as a function of retinal location is included for comparison (From Woodson 1954 data from Osterberg 1935 and Wertheim, 1894)

density is discussed in more detail in the following section In addition to the nonuniform distribution of receptors, there is a region in the normal eye which is devoid of any receptors That is the so-called optic disk (Fig 8 58), where nerve fibers leave the eye to enter the optic nerve and where the retinal circulation enters and leaves the eye This is a region of 3° or more in diameter centered at a point 15° to 17° from the foveal center and with its center just slightly below the nasal horizontal meridian The presence of the blind spot is usually not noticed, even for monocular viewing The reason for this is the fact that it is not associated with a dark region in the visual field but is seen as identical with the surrounding region It is as if the surrounding region "fills in" the blind area in conscious perception The blind spot may readily be demonstrated as shown in Figure 8 63 If the left eye is covered and the small cross is fixated, the black dot will disappear as the page is brought to within approximately 14 inches from the eye It will remain invisible until the cross is to within approximately 10 inches of the eye The vertical extent of the blind spot may be explored by scanning the page vertically along an imaginary line through the fixation cross with the page held at a distance of approximately 12 inches

Information on the optical properties of the eye, at a variety of levels of detail, may be found in a number of recent texts (Brown, 1965a, Le Grand, 1968, Davson, 1962)

THE ANATOMY OF THE VISUAL SYSTEM

The Eye

The eye is enclosed by three membranes, the outer of which consists of the opaque sclera over most of the globe which is continuous with the transparent cornea of the anterior surface of the eye The major blood supply of the eye lies in the heavily pigmented choroid coat directly below the sclera The pigmentation of this layer serves to absorb light within the eye, preventing back scatter, and to reduce entry into the eye except through the cornea and lens At the anterior pole of the eye the choroid coat is continuous with the iris diaphragm, or pupil, and the ciliary body The third, innermost layer of the eye is the retina itself Visual receptors, neural connections of these receptors and additional vascular tissue lie in the retina

THE CORNEA

The cornea is a highly transparent tissue, devoid of blood vessels but well supplied with undifferentiated nerve endings (Fig 8 64) It is nearly 12 mm in diameter, less than a millimeter thick at the center and approximately 1 mm thick at its edges The radius of curvature of its anterior surface is about 7 8 mm , that of its inner surface is approximately 6 8 mm Detailed examination of the structure of the cornea reveals that it is made up of five distinct layers The outermost is continuous with the *conjunctiva*, a membranous covering of the anterior surface of the eye which is folded back on the inside of the eyelids Below the epithelial conjunctive is an elastic layer, *Bowman's membrane* Most of the thickness of the cornea is made up of the *substantia propria* which constitutes nearly 90% of the 1 mm of thickness of this tissue The *substantia propria* itself consists of approximately 60 collageneous layers made up of parallel rows of fibers separated by cell spaces Posterior to the *sub-*

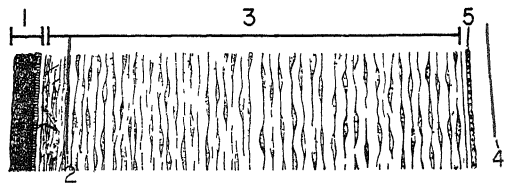

Fig 8 64 Vertical section of human cornea (lying horizontally) *1* corneal epithelium *2* anterior elastic lamina *3* substantia propria *4* posterior elastic lamina *5* endothelium of the anterior chamber

Fig 8 63 Demonstration of the blind spot With the left eye closed fixate the small cross Vary the distance of the page until the black spot disappears The horizontal extent of the blind spot is indicated indirectly by the range of depth in which the black spot is invisible Some indication of the vertical extent of the blind spot may be obtained by scanning the page along an imaginary vertical line through the fixation cross

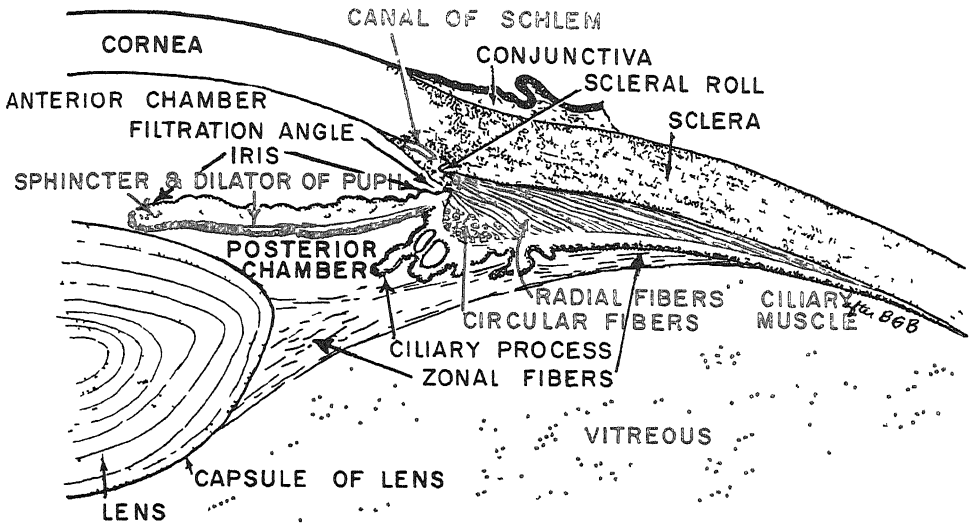

Fig 8 65 Detail of the anterior segment of the human eye (Redrawn from Weymouth 1955)

stantia propria is another elastic layer, *Descemet's membrane*, 5 to 7 μ in thickness The fifth and inner layer of the cornea is the endothelium comprised of flat cells which are in contact with the aqueous humor Although it is without a blood supply, the cornea consumes oxygen at a relatively high rate as a result primarily of epithelial activity (Cogan and Kinsey, 1942, Herrmann and Hickman, 1948)

Although only free nerve endings have been found in the cornea, there is evidence that it may be sensitive to pressure (Rowbotham, 1939), touch, warmth and cold (Lele and Weddell, 1956) The ability of free nerve endings to serve a variety of sensations in other parts of the body is well established (chap 7)

AQUEOUS HUMOR

The transparent fluid which fills the anterior and posterior chambers on either side of the iris diaphragm is formed from blood plasma The blood supply is that to the ciliary body (Davson, 1950) Production of aqueous humor occurs continuously and there must be a route for its drainage from the eye That route is the canal of Schlemm (see Fig 8 65) A complete turnover of aqueous humor occurs approximately once every hour If for any reason the outflow is blocked, continuing production of fluid may cause an increased intraocular pressure Normally, the intraocular pressure is approximately 15 to 18 mm of Hg higher than the intracranial pressure (Adler, 1959) This pressure differential helps to maintain the shape of the eye and, consequently, the appropriate spacing of its optical components

Aqueous humor is similar to blood plasma but contains a lower concentration of protein Metabolic requirements of the crystalline lens and of the cornea are supplied in part by the aqueous humor

THE PUPIL

The relation of the pupil or iris diaphragm to the lens of the eye is portrayed in Figure 8 58 The iris diaphragm is a highly pigmented tissue which arises from the anterior surface of the ciliary body (Fig 8 65) Coloration of the iris results from the nature of the pigment in the front surface of the iris Pigment at the posterior surface is black and helps to reduce light scattering as does the choroid coat.

The sphincter muscle which permits contraction of the pupil forms a ring approximately 0 8 mm in thickness around the pupil It can shorten by nearly 80% of its maximum length in constricting the pupil As mentioned above, its innervation comes from the parasympathetic nervous system The dilator muscles are radial fibers of myoepithelium within the iris These are innervated by the sympathetic nervous system (Adler, 1959) When a bright light is shined in the eye, there is a latency which may be as long as half a second prior to the reflex pupillary contraction The neural pathways which control this reflex must, therefore, involve several neurons Fibers which mediate the response leave the optic tract,

cross the medial border of the lateral geniculate body, and project toward but do not enter the superior colliculus They then travel medially and rostrally to the pretectal region From here, impulses are relayed to the oculomotor nuclei bilaterally and then to the ciliary ganglion (Duke-Elder, 1961) The exact pathway for reflex dilation of the pupil in darkness is not known It does not include the pretectal nucleus The ciliospinal center in the upper thoracic level of the cord is involved and fibers from there pass to the superior cervical ganglion of the sympathetic system Postganglionic fibers innervate the dilator muscles

THE LENS

The lens is a biconvex body which contains neither vessels nor nerves (Figs 8 58 and 8 65) It is made up of many concentric layers of fibrous cells, is approximately 65% water and 6% fat, and contains more protein than any other tissue The lower refractive power of the lens cortex as compared with that of the cornea provides some correction for both chromatic and spherical aberration of the eye The yellowing of the dioptric elements of the eye with age is due primarily to the lens itself (McEwen, 1959) It absorbs nearly 10% of the visible light which enters the eye with the level of absorption being highest at the shorter wavelengths (Weale, 1954) Infrared and ultraviolet light absorbed by lens protein may cause damage Energy for lens metabolism is derived from glucose oxidation Oxygen, ascorbic acid and glutathione are derived from the aqueous humor (Davson, 1949)

The lens is held in place by an elastic capsule, the ciliary zonule (Adler, 1959) (Fig 8 65) With the muscles of accommodation at rest, there is sufficient tension on the capsule to maintain the lens somewhat flattened Contraction of the ciliary fibers through the oculomotor and short ciliary nerves under the control of the parasympathetic system reduces the tension on the lens with a resulting increase in its convexity This permits accommodation for near objects Stimulation of radial fibers via the long ciliary nerves mediated by the cervical sympathetic system can result in accommodation change of as much as 1 5 diopters (Olmstead, 1944) Accommodation to near objects is more rapid than accommodation to distant objects

VITREOUS HUMOR

The vitreous humor is a gel-like substance containing a network of thin fibers of a highly hygroscopic vitrein protein similar to gelatin (Duke-Elder, 1937) With the aid of an electron microscope, it is possible to distinguish the fibrils and interfibrillar substance of the vitreous body of the human eye Fibrils are approximately 67 Å (angstroms) and deviate remarkably little from this size Spherical particles of 100 Å in diameter have also been found (Schwarz, 1961)

THE RETINA

During ontogenetic development, the eye is formed from optic vesicles that arise within the neural groove The optic stalks arise out of the neural tube between the diencephalon and the telencephalon Eyes are formed when the ends of the stalks contact the surface ectoderm The retina is derived out of ectoderm of the neural tube itself It thus has its origin directly out of the central nervous system and its cells may be considered a peripheral extension of the central nervous system Cell development of the retina occurs in stages during the first of which cells arise which migrate outward, eventually to become ganglion cells "Outward" during this development stage is actually "inward" with respect to the eyeball itself as it is finally formed In the next stage of development, the bipolar cells are differentiated, and finally, in the innermost portion of the developing tissue, one of the outer layers of the developed retina, the receptor cells themselves develop

The most prominent aspect of the appearance of the retina is its vascular tissue No vasculature intrudes into the central fovea, that region of the eye which is optimally organized for detailed vision The various retinal layers are thinner in this region (Fig 8 66), ganglion cell bodies are displaced laterally away from the foveal depression and the elongated cones of the central fovea occupy a substantial portion of the retina's thickness In their course toward the optic disk, fibers are deviated around the fovea There is thus a minimum of tissue between the receptor cells and the vitreous humor in the foveal center of the retina (Fig 8 67)

The ten layers of the retina which are frequently discriminated are illustrated schemati-

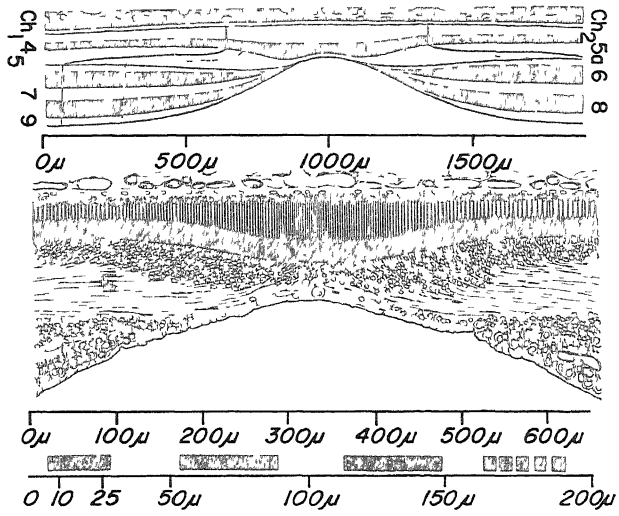

Fig 8 66 Central fovea of the human retina The upper part of the figure is a diagramatic illustration of the arrangement of the layers in the central region Ch choroid coat Numbered layers correspond with the retinal layers as described in the text (From Polyak 1957)

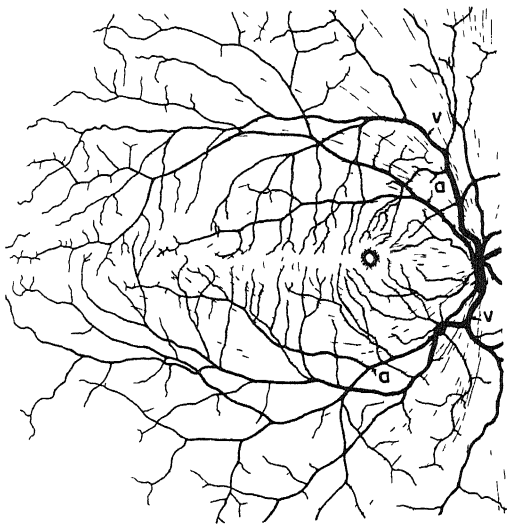

Fig 8 67 Distribution of optic nerve fibers (thin lines) and blood vessels (arteries a veins v) in the retina of an adult *Rhesus macaque* The disc of the optic nerve is at the right margin of the figure The central fovea free of vessels appears to the left of the disc (From Polyak 1941)

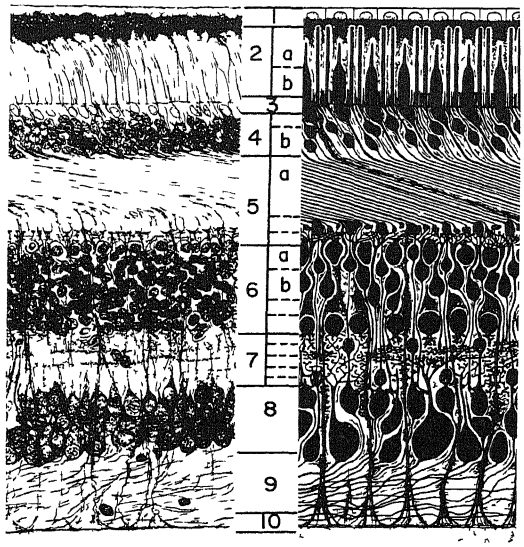

Fig 8 68 Vertical sections of the human retina from the central area midway between the areal periphery and the central fovea Right and left halves of the figure represent different methods of staining The various layers are described in the text (From Polyak 1957)

cally in Figure 8 68 on the basis of microscopic studies with different types of staining Light first enters the retina at layer 10, the inner limiting membrane It then passes successively through the layer of optic nerve fibers, the ganglion cell layer, the inner plexiform layer and the inner nuclear layer The latter contains the cell bodies of bipolar cells and horizontal cells The vessels which supply blood to the tissue of these last three layers are contained in the layers themselves These are the vessels visible in Figure 8 67 The outer plexiform layer contains the fibers from the primary receptors and their synapses with bipolar

and horizontal cells The outer nuclear layer contains the cell bodies of the receptors, the outer limiting membrane separates the region containing the cell bodies of the receptors from their outer segments The second layer is comprised of the outer segments themselves of the rods and the cones The final layer is the heavily pigmented epithelial layer Because light must pass through most of the other layers of the retina before it reaches the primary receptors, the eye of vertebrates is referred to as an inverted eye

It is not possible to say precisely how many receptors are present in the retina of the human eye but frequently quoted figures are 120,000,000 rods and 5,000,000 to 7,000,000 cones (Davson, 1949) Relative distributions of rods and cones are illustrated in Figure 8 62 along with a function which illustrates the visual acuity or spatial resolution capability of the eye, the latter is closely related to the distribution of cones There are no rods in the central foveal region of the retina This region is occupied exclusively by cones, and their number in this rod-free region is somewhere in the neighborhood of 30,000 to 35,000 The angle subtended by the rod-free region at the nodal point 17 mm in front of it is approximately 1° It is convenient to refer to locations on the retina in terms of visual angle rather than actual distance Such a scheme makes it easier to relate the position of an image on the retina to the position of objects in the visual world relative to the point of fixation of vision in the visual world The geometry of the eye is such that a visual angle of 12 sec of arc subtended at the nodal point represents a distance measured along the retina of approximately 1 μ

There are approximately 1,000,000 ganglion cells in the retina, the axons of which comprise the 1,000,000 fibers of the optic nerve It is therefore evident that many receptors must converge on single fibers in transmitting their activity centrally in the visual system There may well be individual ganglion cell pathways available to individual cone receptors of the central fovea, but it is well established that there are many cross connections among receptors within the retina, even in the central fovea

THE RETINAL RECEPTORS

The appearance of rods and two types of human cones based on light microscopy is illustrated in Figure 8 69 The foveal cones are perhaps even more rod-like in appearance than the rods themselves The development of electron microscopy has disclosed many anatomical details of these receptors (Fig 8 70) The receptors in this figure are those of *Necturus*, the mud puppy It is clear that the disk-like structures in the outer segments of the rods differ from those in cones The discs in the rod outer segments appear to be completely separated while those in cones actually represent repeated infoldings of the plasma membrane on the side of the outer segment opposite the ciliary fibrils Primate cones, however, appear to be formed differently (Cohen, 1961, Dowling, 1965) The layers of the outer segments of cones are individual flattened discs just as in rods except that they lack a characteristic rim structure seen in the rods (Fig 8 71) There are no continuities with the plasma membrane in

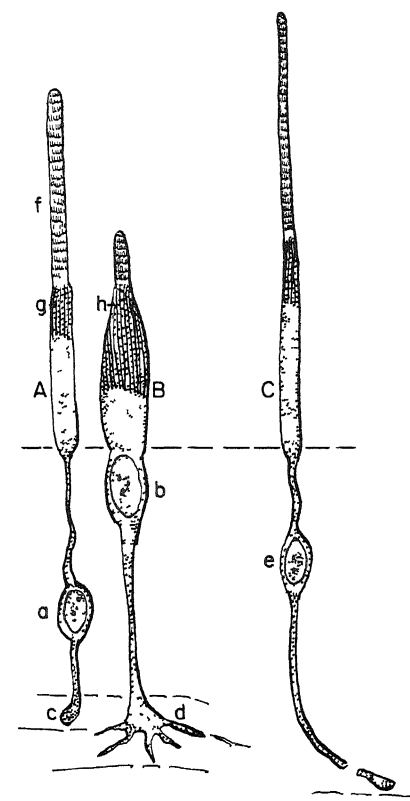

Fig 8 69 Drawings of human rods and cones as seen under light microscopy *A* rod *a* nucleus *c* central connections *g* ellipsoid *f* outer segment *B* cone *b* nucleus *d*, central pedicle *h* ellipsoid *C* cones in the fovea centralis *e* nucleus (Cajal 1904)

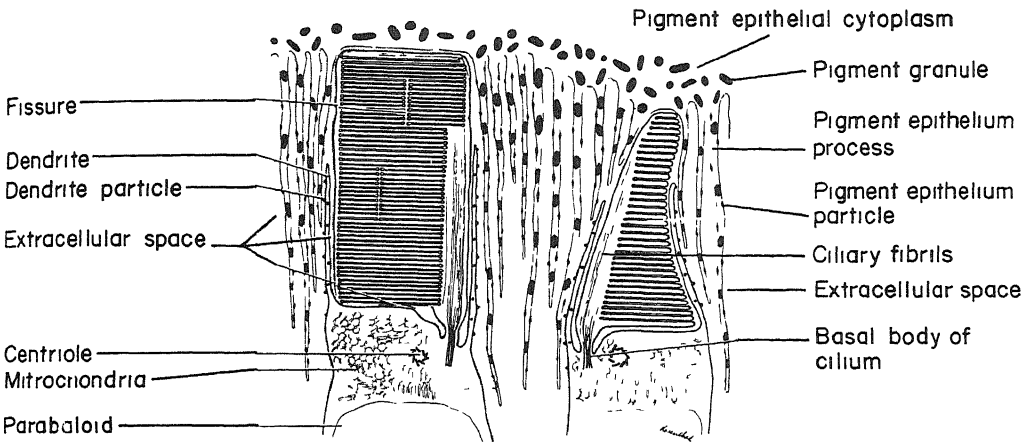

Fig 8 70 Reconstructions of the structures of rods and cones based on electronmicrographs of the receptors of *Necturus* Rods are on the left and cones are on the right All edges of the double membrane discs of the rods appear to have a differentiated rim structure In the cones the disc-like structures appear actually to be continuous in the foldings of a common plasma membrane and lack special limb structure fissures and lamellar micelles seen in the rods (de Robertis 1956)

these sacs as they are seen in the cones of the rhesus monkey The outer segments of foveal cones in the human are only 1 or 2 μ wide and 50 μ long The molecules of photosensitive substance are contained in the outer segments of the receptors The photochemistry of this system is treated below

THE EXTRAOCULAR MUSCLES

The eyes do not remain stationary in the head but move in a highly coordinated fashion Fixation can be maintained on a moving object only by relatively precise conjugate movements of the eyes With changes in the depth of an object viewed, the eyes must converge or diverge appropriately depending on whether the object is approaching or receding The immediate control of movement of each eye is effected by six extraocular muscles (Fig 8 72) Four rectus muscles control movements about two approximately perpendicular axes which are in turn nearly perpendicular to the line of sight with eyes directed straight ahead The lateral or external rectus is located on the temporal side of the eye, the medial or internal rectus is on the nasal side of the eye, with superior rectus at the top of the eye and the inferior rectus at the bottom of the eye Two additional muscles, the superior oblique and the inferior oblique, cause torsional rotation of the eye about the visual axis with some depression or elevation (Fig 8 73)

The Neural Connections of the Visual System

THE RETINA

The advent of electron microscopy has made possible a much better understanding of the nature of neural connections within the retina (Fig 8 74) Observations have been made on the human and on the monkey, cat, rat, rabbit, ground squirrel, and pigeon The basic patterns of cells are similar across species but the detailed nature of their connections differs Receptors make direct synaptic connection with bipolar cells and also with horizontal cells Horizontal cells in turn make synaptic connections with bipolar cells over a lateral extent such that they provide a mechanism for spatial interaction among different receptors A bipolar cell may make contact with a number of receptors directly in addition to receiving effects from more distant receptors via horizontal cells The inner terminations of bipolar cells are usually dual in nature and have been called *dyads* In man and the monkey, the dyad terminations from a single bipolar cell are usually on a ganglion cell and an amacrine cell There are considerable differences in the nature of these connections among species In the pigeon and the frog, there are relatively few direct terminations of bipolar cells on ganglion cells Information from bipolar cells is much more often mediated by

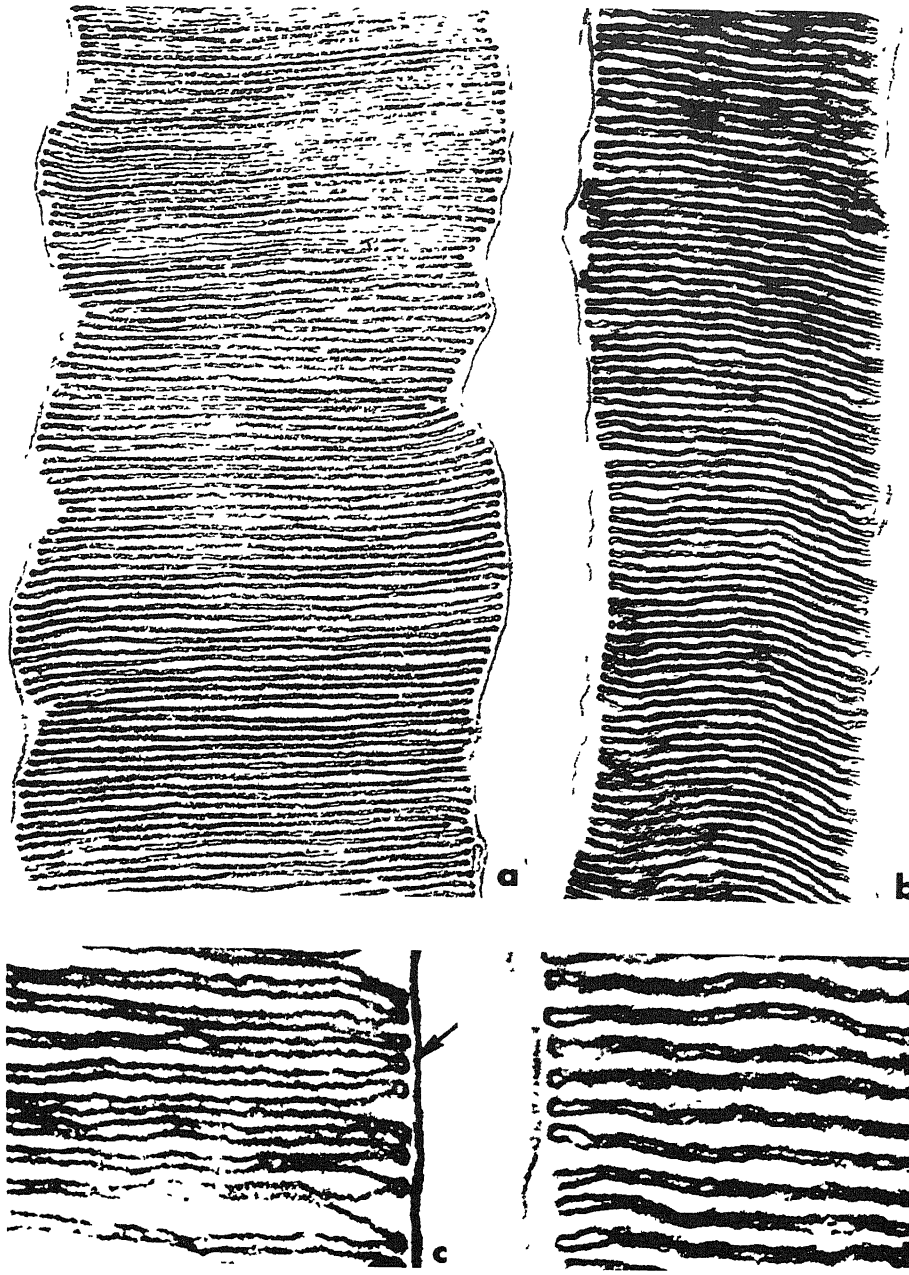

Fig 8 71 Electron microphotographs of longitudinal sections of the outer segments of a rat rod (*a*) and of a foveal cone of the rhesus monkey (*b*) The double membrane discs are similar in each of these structures showing no continuities with plasma membrane or with each other (amplification × 50 000) The outer segments of a rod (*c*) and a cone (*d*) of a monkey retina are shown at higher magnification (× 150 000) below The double membrane discs of the rod and cones differ only in that the rod membranes may be slightly thinner and their edges possess a characteristic rim structure as shown by the arrow (From Wald and Brown 1965)

amacrine cells This is true to a lesser extent in the ground squirrel and the rabbit It is still less so in the cat There may be little difference between the monkey and the human, with very many fewer bipolar to amacrine contacts, certainly in the region of the fovea, than is true for much lower animals Differences in synaptic connections among bipolar cells,

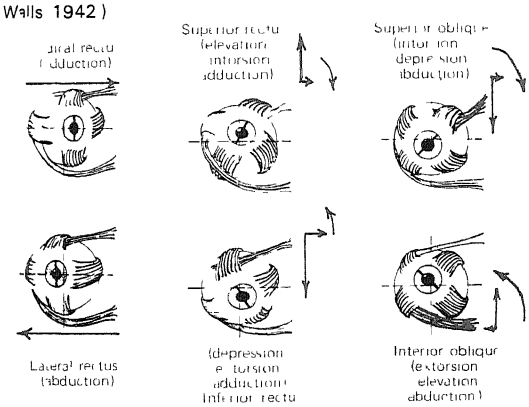

Fig 8 73 Action of the three pairs of antagonistic eye muscles (Adler 1965)

amacrine cells and ganglion cells which have been observed with the electron microscope may be correlated with functional differences in the neural activity of the retina as described in a later section

THE OPTIC NERVE AND OPTIC TRACT

The spatial organization of the retina is preserved in the pattern of orientation of fibers which leave the eye in the optic nerve (Fig 8 75) Fibers that represent signals originating in the temporal retina do not cross the midline at the optic chiasm but travel up into the optic tract on the same side of the brain Fibers originating in the nasal half of the retina, on the other hand, depart from those fibers which represent the temporal half, cross at the chiasm and travel centrally within the optic tract on the opposite side of the brain The implications of these connections have been tested by observing the effects of lesions made in the regions indicated in Figure 8 75 The major import of this anatomical design is that stimulation of receptors from objects within the right half of the visual field will stimulate the left half of each retina and will give rise to nerve signals which will be transmitted to the left hemisphere of the brain Conversely, stimulation from the left visual field ultimately is transmitted to the right hemisphere of the brain

The fibers within the optic tracts terminate in various places Some go to the pretectal region (Magoun and Ranson, 1935a and 1935b) and others to the superior colliculus (Davson, 1949) Most terminate in the lateral geniculate body

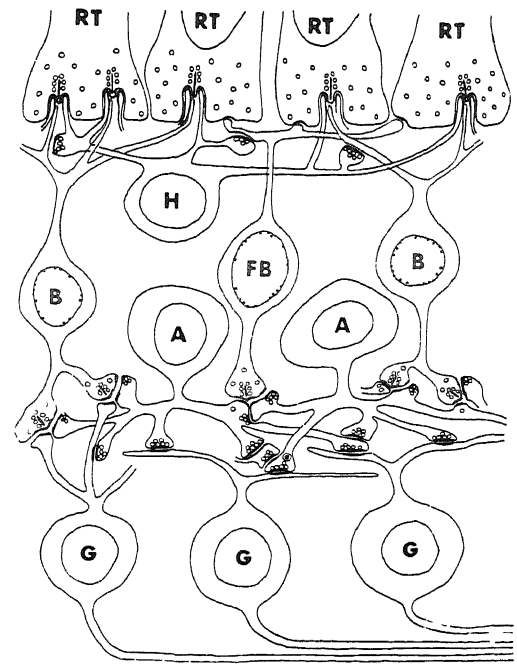

Fig 8 74 The synaptic contacts of vertebrate retinas The receptor terminals (RT) are penetrated by processes from bipolar (B) and horizontal (H) cells which terminate near the synaptic ribbons of the receptors Flat bipolar cells (FB) make superficial contacts on some receptor terminals Horizontal cells make synaptic contacts with bipolar dendrites as shown and with other horizontal cell processes as well Horizontal cells appear to mediate connections between receptors and bipolar cells over relatively great lateral separations on the retina In the region corresponding to the inner plexiform layer bipolar terminals are shown to contact either one ganglion cell (G) dendrite and one amacrine cell (A) process at ribbon synapses or two amacrine cell processes Amacrine cells make synapses with each other with ganglion cells and back onto bipolar terminals The relative number of direct contacts between bipolar cells and ganglion cells appears to increase the higher the level of the animal considered (Dowling 1970)

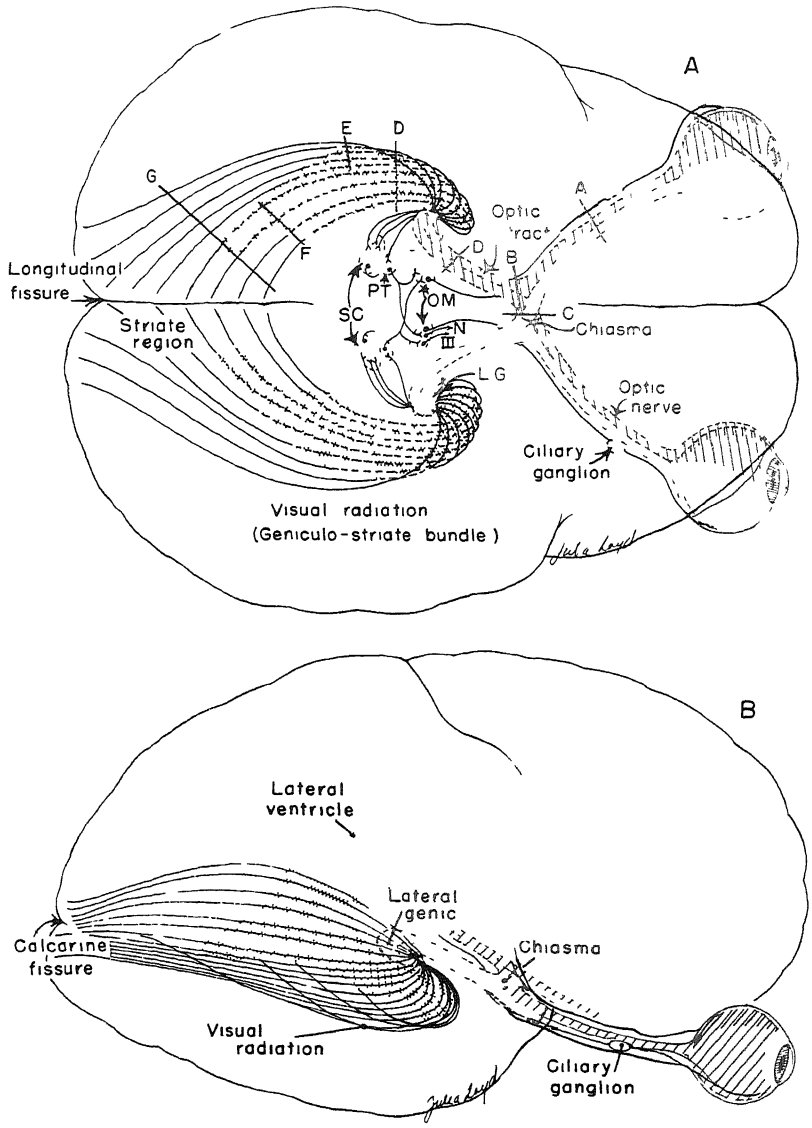

Fig 8 75 Diagram of the central visual pathways *A* plan view visual defects corresponding to lesions A B C D E F G are described in the text S C superior colliculus P T, pretectal region O M oculomotor nucleus L G lateral geniculate *B* elevation view (Brown 1965a, as modified from Homans and Fox and German)

THE LATERAL GENICULATE BODY

Cells of the dorsal nucleus of the lateral geniculate body are in six layers, the first, fourth, and sixth receiving fibers from the contralateral eye, and the second, third, and fifth receiving fibers from the ipsilateral eye (Fig 8 76) There is topological correspondence between points on the retina and areas of termination in the lateral geniculate body (Clark and Penman, 1934) Although there is some evidence for binocular fusion of neural activity at the lateral geniculate body for the cat (Hayhow, 1958, Sanderson et al , 1969), there seems to be little binocular interaction at this level in the monkey or, presumably, in man. Recent information from the laboratory of Peter Bishop suggests that there may be binocular interaction in cells of the lateral geniculate body If this is so, it is possible that it is mediated for at least one eye via cortical connections In

Fig 8 76 Section through the left lateral geniculate body of a rhesus monkey sacrificed 8 months after enucleation of the left eye (Brindley 1960 after Minkowski)

monkeys, neural fibers reaching the lateral geniculate body divide into several branches, each of which may terminate on a different neuron There is thus considerable divergence from retina to lateral geniculate The fact that there are approximately as many cells in the lateral geniculate body as there are fibers reaching it via the optic tract suggests that

there must also be convergence on single cells of the lateral geniculate body The idea that there is only a single input to each cell (Glees and Clark, 1941) is difficult to accept Various authors have suggested differential functions for the several layers of the lateral geniculate body (DeValois, et al , 1958, Clark, 1949) but the possible differentiation of their roles remains in doubt

CORTICAL CENTERS FOR VISION

The radiation fibers from the lateral geniculate body project to the striate cortex of Area 17 of the occipital lobe via the geniculostriate bundle This bundle, the visual radiation, travels forward and laterally then down around the ventricle of the temporal lobe before reflecting back and upward to the occipital cortex (Fig 8 75) That a topologic organization of the individual fibers with respect to retinal origin of their signals is maintained can be demonstrated by sectioning the optic radiation as illustrated in Figure 8 75 The effects of sections in various regions throughout the neural pathway are of interest As shown in the figure, a section of one optic nerve results in complete blindness of one eye (*A* in Fig 8 75) A transverse cut on one side of the optic chiasm (*B*) will result in blinding of the temporal half of the retina on the same side and possibly the nasal half or a portion of it for the retina on the opposite side If a medial section of the optic chiasm is made (*C*), both nasal retinas are blinded Section of the entire optic tract on one side (*D*) results in blinding of the half of the retina of each eye on the same side as that on which the section is made A section of the entire geniculostriate bundle has the same result If the upper bundle is cut on one side (*E*), there is blindness in the upper retinal quadrants in both eyes on the same side as the cut A cut in the lower portion of the bundle (*F*) produces blindness of the lower retinal quadrants on the same side

The striate area of the occipital cortex (Area 17) extends along the upper and lower lips of the calcarine fissure The way in which radiation fibers which represent various retinal regions terminate in the cortex is portrayed by the coding of the cortex and the retinal field as shown in Figure 8 77 There is a disproportionately large number of cortical cells which subserve the processing of information from the macular region of the retina It has been

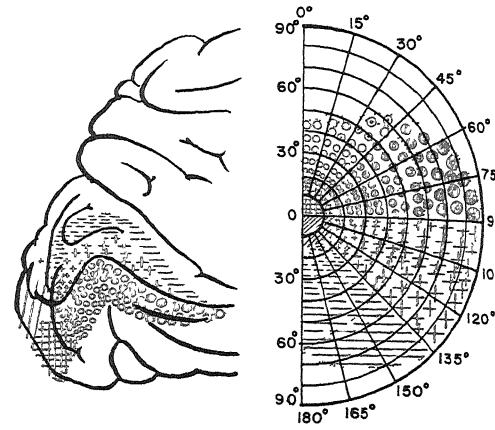

Fig 8 77 *A* projection of the retina on the visual cortex Various regions of the visual field (*B*) referred to regions in the striate area (*A*) as indicated by the coding The figure is drawn with calcarine fissure spread apart to reveal its inner walls (From Holmes 1945)

estimated that there are on the order of 100 cortical cells for every cone in the fovea of the eye of the monkey (Marshall and Talbot, 1942) The widespread representation of the central area of the retina renders vision for this part of the visual field relatively unaffected by even severe lesions of the occipital lobe Areas 18 and 19 of the occipital cortex receive projections from the striate area and have been assigned associative and motor functions (Chow and Hutt, 1953)

EFFERENT PATHWAYS

Efferent fiber pathways within the visual system have been well established anatomically in birds, but their presence in man is uncertain and their function, even when they are known to exist is not at all clear (Brindley, 1960) It has been shown recently that the relation between excitatory and inhibitory processes in the retina of the chick is disturbed by electrical stimulation of centrifugal fibers (Miles, 1970)

INTERMODALITY EFFECTS

A variety of stimuli from other sensory modalities such as hearing, smell, and the vestibular sense may influence the response of the visual system (Hernández-Peon, et al , 1957) Such influences may be mediated via the retic-

ular formation (Granit, 1955) There is a variety of evidence for involvement of regions of the nervous system not classically associated with the visual pathways in response to visual stimulation For example, units in the ventral medial hypothalamus of cats have been reported to show an increase in firing rate in response to visual stimulation by diffuse light or shadows (Campbell, et al , 1969) Several investigators have shown that unit activity in the amygdaloid nucleus is influenced by visual stimulation (Sawa and Delgado, 1963, O'Keefe and Bouma, 1969) A variety of responses to visual stimulation has been recorded from the inferotemporal cortex Recently, complex forms of response to visual stimulation have been recorded in single units of this area (Gross, et al , 1969) The posterior cingulate gyrus has been implicated with the visual system by the demonstration that effects on cortical dendritic branching in this region may occur as a result of dark rearing (Coleman and Riesen, 1968) The red nucleus is implicated in visual processes by reason of the fact that its destruction may cause a deterioration of the ability to make visual size discriminations (McNew, 1968) As mentioned above, inputs from a number of other sensory modalities may influence visual responses The simple expedient of tilting the body appears to change the orientation of receptive fields for visual stimuli in the occipital cortex (Horn and Hill, 1969)

There is a variety of evidence that regions of the nervous system which have classically been assigned an exclusive role in connection with some sense modality may, in fact, be involved in a variety of sensory functions Monkeys which had been peripherally blinded earlier were able to perform a locomotor maze task in which they were required to move through the maze After lesions were made in the striate cortex their performance was impaired Their performance in a stylus maze task in which total body movements were not required showed no impairment (Ohrback, 1959) The implication is that various regions of the cortex, including those classically assigned a visual function, may play an important role in the organization and control of behavior in the absence of any stimulation via the classically associated sensory modality Knowledge of the functional anatomy of the nervous system can be characterized only as primitive at this time

PHYSIOLOGY OF VISION

Photochemistry

The initial transformation of radiant energy in the eye which results ultimately in vision involves the absorption of light quanta by molecules of photosensitive substance It has been known for years that the light sensitive material for rods in many organisms including the human is rhodopsin (Wald and Brown, 1958) The relative spectral response of the eye when dark adapted or under conditions of low illumination for regions of the retina which abound in rods agrees well with the absorption spectrum of this pigment as shown in Figure 8 78 (cf , V'_λ, Fig 8 57) The photochemistry of bleaching and regeneration of rhodopsin in the visual process has been worked out in great detail by Wald and his colleagues (Wald and Brown, 1965)

The visual pigments involved under conditions of higher light illumination, those pigments which reside in the cones, are not understood nearly so well as is rhodopsin It had long been assumed that there were perhaps

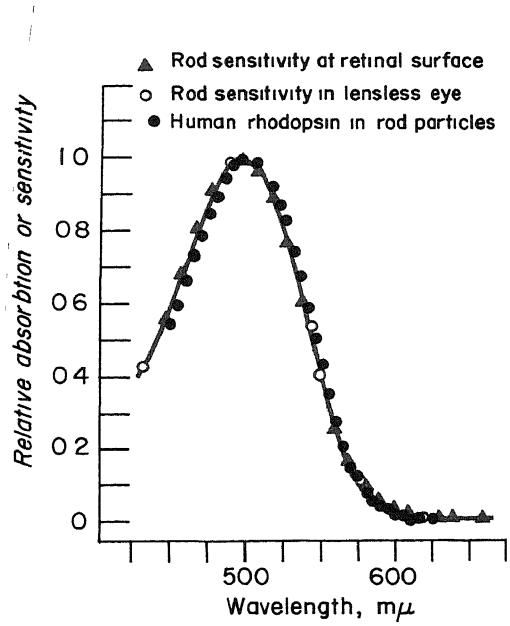

Fig 8 78 Absorption spectrum of human rhodopsin measured in a suspension of rod outer segments compared with the spectral sensitivity of human rod vision The latter data have been corrected for ocular transmission or are based on measurements of the spectral sensitivity in aphakic (lensless) eyes (From Wald and Brown 1958)

three pigments, based on the trichomacy of vision (discussed in a later section) Only recently, however, have we had fairly direct evidence as to the existence of three different classes of pigment which probably reside in each of three different classes of cone receptors The spectral response function of the light adapted eye, measured in the fovea, provides a basis for the specification of the units of light as discussed earlier It also is believed to represent some form of composite absorption spectrum for the cone pigments

SPECTRAL ABSORPTION FUNCTIONS OF VISUAL PIGMENTS

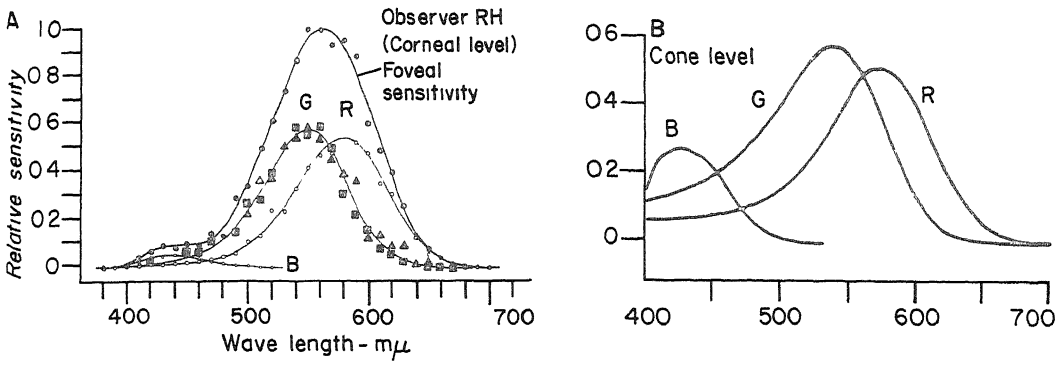
Several different approaches to the determination of the nature of pigment absorption characteristics have been taken in addition to extraction and in vitro measurement First, it is possible to measure the spectral response function V_λ, as illustrated in Figure 8 57 This is the composite function for all cone pigments If the eye is then exposed to a steady background illumination of intense blue light which tends to bleach out the pigments with peak absorption in the middle and short wavelength regions, the resulting spectral response function may be assumed to represent the absorption spectrum of a long wavelength pigment The absorption spectrum of a pigment which peaks in the middle wavelength may be revealed by measurements against a background of mixed long and short wavelength, or a purple light The nature of the spectral absorption function of a pigment which absorbs maximally in the short wavelength region may be inferred from measurements made with the eye adapted to a highly intense yellow light which bleaches out pigments of both long and middle wavelength absorption spectra The results of such measurements are discussed in detail in the treatment of color vision

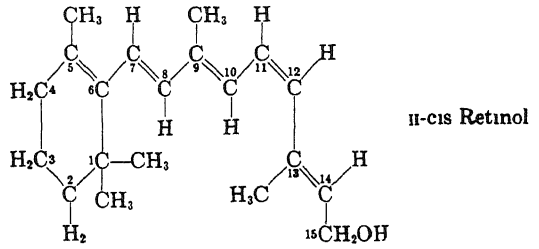
Measurements of this kind show an approximate agreement with other measurements based on the computation of difference spectra after selective bleaching (Brown and Wald, 1963) They are also in agreement with results which have been obtained in the living human eye by an objective measurement of the light reflected back out of the eye for various wavelengths of illumination following selective bleaching When appropriate account is taken of the fact that such light has made two passes through the retina, it is possible to compute the absorption spectrum for the unbleached eye, and, after bleaching, difference spectra which may represent individual pigments Although this technique has the advantage of providing objective records on the living human eye, the interpretation of results involves a number of complications (Rushton, 1964)

Another interesting and extremely difficult technique involves the measurement of spectral absorption characteristics of pigments within individual cells The technique is known as microspectral densitometry Its difficulties are such that only a few investigators have undertaken it and data are available on only a very few individual cones from the human retina (Marks et al, 1964, Brown and Wald, 1964) Those data which are available tend to agree with data based on selective adaptation or selective bleaching of the human retina One set of curves which provides a representative summary of the relations among the absorption spectra of what are believed to be three retinal cone pigments and the composite cone sensitivity function is presented in Figure 8 79 The data points in the figure are based on measurements at the cornea When selective spectral absorption of various ocular media is taken into account, the relative shapes of the cone functions are changed slightly This is shown on the right half (*B*) of Figure 8 79 The primary difference is an elevation in the relative amplitude of the short wavelength function This results largely from the blue absorbing properties of the yellow macular pigment The peak values for the functions presented are at 430, 540, and 575 nm The hues which correspond with these wavelengths are a blue, a green, and a yellow Thus, the long wavelength "red" pigment really has its maximum absorption in the yellow region of the spectrum, although it extends well into the longer wavelength red region

PHOTOCHEMICAL CYCLES

The photochemical cycles for a large variety of visual pigments in a number of organisms appear to be remarkably similar (Wald, et al, 1963) Each pigment is identified with its own specific type of protein, an opsin which is united with the eleven-*cis* isomer of retinaldehyde Retinaldehyde is the chromophore of the complex molecule and it is on this portion of





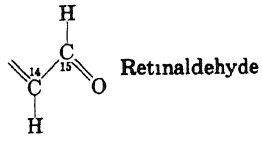


Fig 8 79 *A* individual color receptor mechanisms and total foveal sensitivity of observer RH The relative amplitudes of the sensitivities of the individual receptor mechanisms are based on measurements at the corneal surface *B* relative amplitudes as they would be found at the cones In the average observer the blue component would be only about one-third as high as the amplitude found in RH (From Wald and Brown 1965)

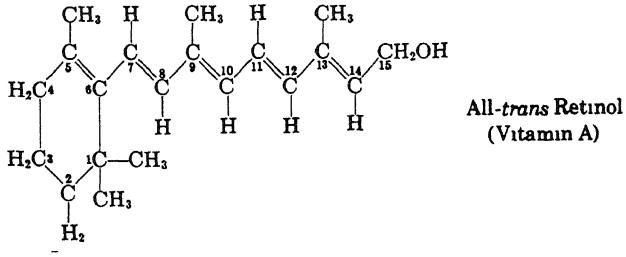

Fig 8 80 Molecular structures of 11-*cis* Retinol retinaldehyde and all-*trans* Retinol (vitamin A)

the molecule that the light acts The nature of the action is solely to transform retinaldehyde (illustrated in Fig 8.80) from the eleven-*cis* to all-*trans* configuration (Hubbard and Kropf, 1958) The all *trans* retinaldehyde is initially still bound to the unmodified opsin of the photopigment This molecule is extremely unstable at ordinary temperatures, however, and in darkness is transformed rapidly over a series of intermediate products In the rhodopsin cycle, the first product of bleaching is known as prelumirhodopsin, which is transformed rapidly into lumirhodopsin The next stage is metarhodopsin I, then metarhodopsin II, and finally, as a result of hydrolysis, a mixture of opsin and free all-*trans* retinaldehyde. The last stage is so slow that it cannot play a direct role in visual excitation. Therefore, excitation

must depend upon one of the intermediate stages In the presence of an enzyme, alcohol-dehydrogenase, the all-*trans* retinaldehyde is reduced to retinol (vitamin A) Regeneration of the original retinal pigment requires a re-oxidation of retinol to retinaldehyde along with isomerization to the eleven-*cis* configuration A schematic illustration of the various stages of bleaching is presented in Figure 8 81 for rhodopsin The stages are probably similar for other pigments except that the unique opsins which characterize the pigments replace the opsin portion of the rhodopsin molecule Another form of retinaldehyde which differs from that found in mammals has been found in fish The difference consists in an extra double bond in an ionone ring Combination of the various opsins which have been found in naturally occurring photopigments with both of the types of retinaldehyde has resulted in the production of a variety of photopigments including some which have not been found in nature

The spectral absorption characteristics of photopigments when plotted on a wave number axis have all been shown by Dartnall (1957) to be of approximately the same form That is, if they are shifted along the wave number axis, they may be superposed The absorption spectra of these same pigments plotted on a wavelength axis are broader, the longer the wavelength at which they absorb maximally The examination of the way in which pigments combine and a variety of calculations may be simplified if absorption spectra are expressed with respect to the wave number axis

The bleaching and regeneration cycle does not invariably go through the stages outlined above A portion of certain unstable intermediate products is isomerized back into photosensitive forms by the direct action of light (Dowling and Hubbard, 1963) This rapid regeneration of a photosensitive substance from the unstable photoproduct may account for the fact that it is never possible to bleach more than half of the rhodopsin in the retina for relatively short duration exposures of a bleaching light, no matter how intense it may be (Hagins, 1956)

ABSOLUTE RETINAL SENSITIVITY

It has been estimated that the number of pigment molecules in an individual rod may be 70,000,000 or more (Pirenne, 1962) for each of the 120,000,000 rods in the human retina Each of these molecules may catch a quantum of energy It is of importance for our understanding of how the visual system works to examine the question of how much energy is necessary for the excitation of a conscious response to retinal illumination A number of investigators have studied this problem over the years, but not until around 1940 was an experiment performed which carefully considered all of the variables which must be controlled for the measurement of a truly minimum energy requirement (Hecht et al , 1942)

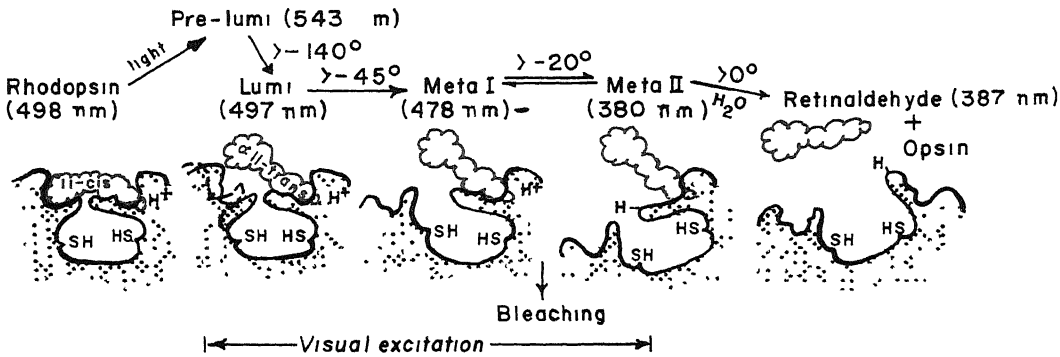

Fig 8 81 Stages in the bleaching of rhodopsin The chromophore of rhodopsin 11-*cis* retinaldehyde fits closely a section of the opsin structure The only action of light is to isomerize retinaldehyde from the 11-*cis* to the all-*trans* configuration (prelumirhodopsin) Then the structure of opsin opens progressively (lumi- and the metarhodopsins) ending in the hydrolysis of retinaldehyde from opsin Bleaching occurs in going from metarhodopsin I to II and visual excitation must have occurred by this stage The opening of opsin exposes new chemical groups including two -SH groups and one H+-binding group The absorption maxima shown are for prelumirhodopsin at −190° C lumirhodopsin at −65° C, and the other pigments at room temperature (Wald and Brown 1965)

The eyes of observers were dark adapted for at least thirty minutes in order to ensure maximum sensitivity of the rod receptors A test light wavelength of 510 nm was selected because this wavelength corresponds approximately with the wavelength of maximum absorption of the photopigment of the rods, rhodopsin The test flash illuminated a region of the retina located at a distance of 20° temporally along the horizontal meridian of the retina In this region the density of rods is at a maximum and there is no danger of complication by the blind spot (Fig 8 62)

Retina Image Size. The size of the image of the test flash on the retina was restricted to 10 min of arc in diameter It has been demonstrated that with increase in the area of a test patch on the retina, retinal illumination, expressed in lumens per unit area, may be reduced Within limits, the eye is capable of summation of light energy over its surface Thus, if a given total energy is required for stimulation of the eye, a lower number of lumens per unit area may be required if a larger area is illuminated (Bartlett, 1965a) This summation capability begins to break down if the area becomes too large, however There is a limit to the extent to which light may be dispersed over the retina without a reduction in the summation of its effectiveness The area selected by Hecht, Shlaer, and Pirenne (1942) was well within the limit for complete retinal summation

Test Flash Duration The flash duration which they employed was 0 001 sec Just as the eye is capable of summating energy over area, so it is also capable of summating energy in time Within limits, the longer the duration of a test flash, the lower will be the threshold level expressed in lumens The lumen is a unit of luminous energy per unit time or luminous flux Thus, the longer the eye is exposed to a given luminous flux, the greater will be the total energy of the exposure If threshold depends upon a fixed amount of energy, then the longer the flash duration, the lower will be the luminous flux necessary to achieve the constant energy required for threshold (Fig 8 82) This is true as long as a critical duration, beyond which temporal summation is no longer possible, is not exceeded (Graham, 1965a) Critical duration in the dark-adapted eye is approximately 0 1 sec The flash duration of 0 001 sec was therefore well within the critical duration

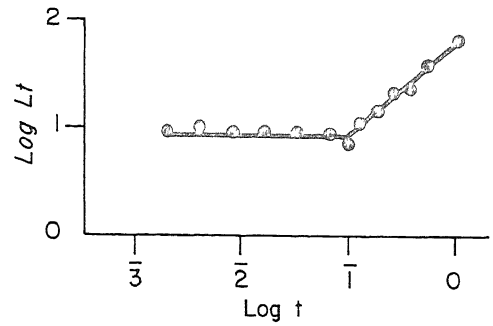

Fig 8 82 Logarithm of the product of luminance and flash duration as a function of the logarithm of flash duration for a small test light in the fovea Time is in seconds The product of luminance and time or energy remains constant up to a flash duration of 0 1 sec and then increases in direct proportion to duration (Graham 1965a)

Minimum Energy at the Retina. The apparatus used for the experiment was carefully calibrated in terms of radiant energy per unit time per unit area delivered to the corneal surface of the eye of an observer Precautions were taken to insure that the cross-sectional area of the beam entering the eye was known and was in no way restricted or altered by pupillary contraction Threshold measurements revealed that the test flash could be detected at significantly better than a chance level when between 54 and 147 quanta were supplied at the corneal surface By taking into account the absorption and reflection characteristics of the ocular media and the percentage of energy reaching the retina which is actually absorbed by the photopigment, it was estimated that the number of quanta necessary for excitation of the visual process in a human observer lies somewhere between 5 and 14 The best available current estimate of the number of rods in the retinal area which was stimulated is 350 The 5 to 14 quanta may be expected to be distributed randomly over such an area and, consequently, there is a negligible probability that more than a single quantum would be absorbed by a single rod at threshold

This is a highly significant finding It means that the action of a single quantum on one out of more than 70,000,000 molecules within a given receptor gives rise to events in that receptor which influence succeeding elements in the nervous system and ultimately arouse a conscious response The fact that not one but at least a small number of rods must be excited in the same short interval of time is also

significant Some molecular transformations may be expected to occur in the absence of light The requirement that a finite number, perhaps five, occurs within a short time interval provides the organism with a basis for the discrimination of true signals against the background noise level of the retina

Sources of Variability It is appropriate to mention one additional implication of this experiment It was observed that the variability of response of the subjects was only very slightly greater than the quantum variability to be expected in repeated presentations of the stimulus This implies that under very carefully controlled conditions, the physical variability of the stimulus may represent a major contribution to the total variability of the stimulus-response system

Physiology

ELECTRICAL ACTIVITY

The Electroretinogram. The recording of gross electrical activity of the retina in response to light stimulation has been possible for a number of years (Riggs, 1958, Gouras, 1970) If a voltage is measured between the front surface of the eye in the region of the cornea and a reference electrode located on the forehead or some region of the face, stimulation of the eye by light results in a complex wave form of response which occurs after a relatively short latency (Fig 8 83) A contact lens is used to position an electrode over the cornea Certain components of the wave form are associated with scotopic or rod processes and other components are associated with photopic or cone processes The wave form changes depending on the condition of adaptation of the eye when the stimulus is presented, whether a single stimulus or a train of stimuli is presented, and such variables as the luminance and wavelength distribution of the stimulus Although the components of the electroretinogram (ERG) may represent rod and cone processes, this does not necessarily imply that they reflect voltage changes within the receptors themselves The latency of response of some of the components is much too long for that and it is probable that the major components of the ERG, as it has been typically recorded, reflect events which are triggered by the stimulation of receptors but which occur in subsequent elements of the visual pathway within the retina

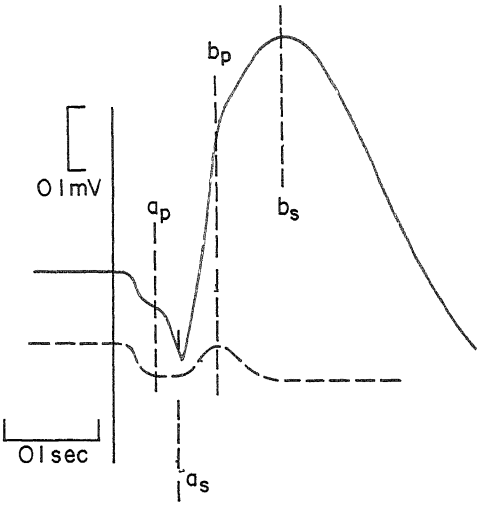

Fig 8 83 The electroretinogram in the dark-adapted human eye (solid line) as the resultant of photopic (dashed line) and scotopic (dotted line) components The a-wave is composed of the photopic (a_p) and scotopic (a_s) components and the b-wave is composed of the photopic (b_p) and scotopic (b_s) components (Armington et al 1952)

The Early and Late Receptor Potentials In recent years (Brown, 1968) it has been demonstrated that electrical activity of the retina, which almost certainly has its origin in the receptors themselves, may be recorded In animals, these components may be seen when an electrode is inserted into the eye and into the retinal layers an appropriate depth The voltage change which occurs in response to light stimulation is measured with respect to a second reference electrode, the tip of which is located in the vitreous humor of the eye Under these circumstances two components are revealed, one of which is of almost zero latency and the second of which occurs approximately 1 msec after the stimulus These have been called the early and late receptor potentials (ERP and LRP), respectively (Fig 8 84) The first is associated with the physical events which accompany the absorption of quanta by the photopigment The significance of the late receptor potential is unknown, but presumably it is associated with the events which result from quantal absorption and which precede or cause excitation of the neural elements in the system

The early and late receptor potentials of the retinal response can be observed in human subjects if an appropriate technique is em-

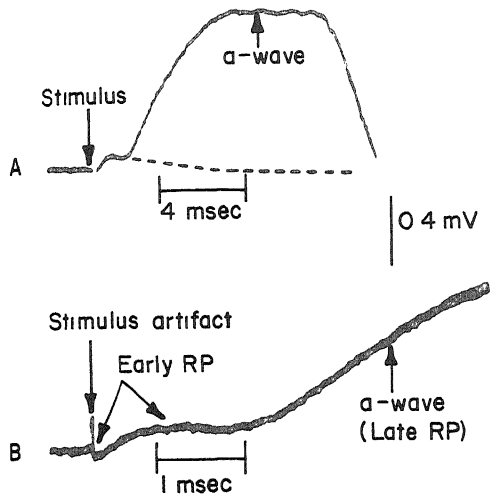

Fig 8 84 The early and late receptor potentials of the cynomolgus monkey The top record *A* is from the peripheral retina and shows the early response between the occurrence of the stimulus flash and the rising phase of the a-wave The course of decay of the early response which can be isolated by cessation of artificial respiration is shown by the dashed line The bottom record *B* is from the fovea where the response is somewhat larger in amplitude The stimulus artifact is only positive and thus the early receptor potential is seen to be biphasic The late receptor potential corresponds to the rising phase of the a-wave (Brown 1968)

ployed Obviously, it is not possible to pierce the eyeball with a recording electrode A conventional method of recording the electroretinogram may be combined with a computer averaging technique for the purpose, however An electrode is mounted in a contact lens such that it can be located over the corneal surface of the eye A light flash is presented repeatedly and the response to each successive flash is accumulated in an appropriate computer system This process is synchronized with the time of presentation of the flash Those electrical events which invariably occur at a certain time following the initiation of a flash tend to summate as the number of flashes is increased Random events which are not directly correlated with the flash tend, on the other hand, to cancel each other out It is thus possible, after a sufficient number of presentations, to visualize components of the electrical response which could never be seen by recording only a single response

Changes in the early receptor potential are approximately proportional to changes in the physical energy of stimulation On the other hand, changes in the late receptor potential are, over a substantial range, proportional to the logarithm of the stimulus intensity Stimulus intensities may be reached beyond which the response no longer increases This is to be expected when levels of illumination are employed which result in substantial bleaching of the photopigment The interesting point is that the late receptor potential shows a relation to the stimulus which is similar to the relation between response and stimulus of a human observer in psychophysical experiments The effectiveness of an increase in stimulation is more nearly directly related to the ratio of the increase than the absolute amount of the increase There is also a breakdown of this relation as higher stimulus levels are achieved The conclusion which may be drawn is that significant aspects of the transformation which occurs between peripheral stimulation and a complex response to sensory inputs occur at the level of the receptors themselves Additional implications of this finding are considered in connection with adaptation of the eye

Recently, it has been demonstrated that the early receptor potential is dominated by the cones in human vision (Goldstein and Berson, 1969, 1970) Changes in the early receptor potential which are associated with inherited retinitis pigmentosa have also been found (Berson and Goldstein, 1970)

RETINAL INTERACTION EFFECTS

There are many lateral interconnections among the pathways from individual receptors to the layer of ganglion cells and subsequently to higher visual centers of the brain (Fig 8 72) If a spot of light stimulates one retinal region, effects of such stimulation may occur in surrounding regions as a result of the activity of horizontal or amacrine cells It would be of very great interest to be able to record from each of the classes of cells in the retina during stimulation in order to determine the way in which their responses compare and what sort of interaction mechanisms exist Unfortunately, this is a very difficult task Intracellular recording with electrodes of very small diameter (less than 1 μ) has been accomplished in each of the various types of cell in the retina of *Necturus*, the mud puppy The job is easier in *Necturus* by reason of the relatively large size of the individual cells (Fig 8 85) A black bar in this figure represents illumination of one receptor The response of the receptor is a

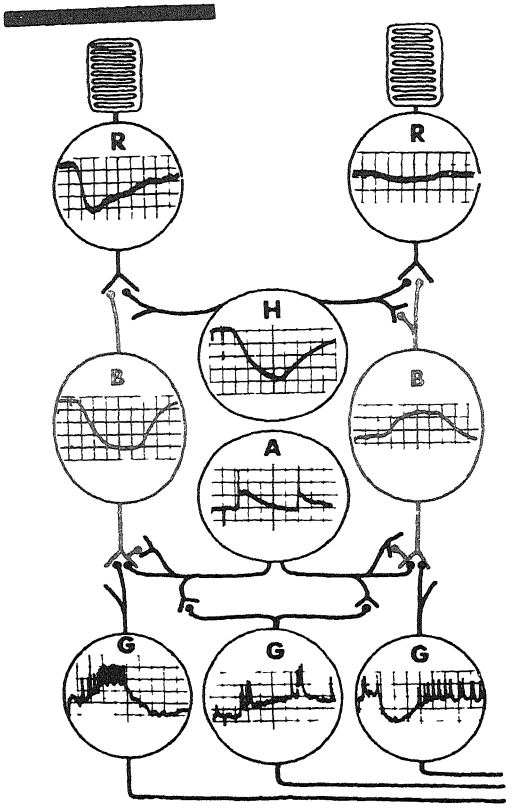

Fig 8 85 Intracellular responses of various retinal elements to stimulation of an isolated retinal region R receptors H horizontal cell B bipolar cells A amacrine cell G ganglion cells The stimulation is indicated by a black bar over the left receptor The responses of the receptor stimulated and the bipolar and horizontal cells in direct contact with it are shown to be hyperpolarization The action of the horizontal cell on the bipolar cell which it contacts is apparently to cause depolarization Spikelike discharges are first seen at the level of the amacrine cells but the spikes are single transients which occur only at onset and termination of illumination Typical neural spike discharge is first seen at the level of the ganglion cells (Dowling, 1970)

graded potential and varies in level with respect to the amplitude of stimulation Although the initial response may be somewhat higher than the final sustained response, the response does not decay completely as long as the stimulus is left on Perhaps surprisingly, the nature of the response is one of hyperpolarization Instead of a reduction in the level of the membrane potential, this is increased Hyperpolarization appears to be typical of the receptors themselves, the horizontal cells and the bipolar cells Although studies of neural tissue would not have led one to predict this outcome, one must infer that hyperpolarization of certain elements within the nervous system may somehow be associated with excitation of succeeding elements with which they are in contact

Lateral Inhibition. A receptor displaced laterally from that which directly receives stimulation may show little or no response Such response as is observed could be attributed to the effects of scattered light within the eye The bipolar cells connected to the adjacent receptors do show a response, however, and it is of opposite polarity to that of the bipolar cells which are directly connected with the stimulated receptor This lateral projection onto bipolar cells would thus appear to be inhibitory in nature The time course of the effect is similar to that of the effect measurable in the receptors themselves and in the horizontal cells and hence the pathway for such lateral inhibition would seem to be via the horizontal cells Amacrine cells provide a horizontal or lateral linking pathway, but they respond with a transient It is thus difficult to understand how they might mediate the graded depolarization observed in adjacent bipolar cells

Some bipolar cells have been found in the mud puppy for which the graded potential is in the direction of depolarization The response of either type of bipolar cell to a small spot of light stimulation is reduced or antagonized when additional illumination is added around the region of the central spot There thus appears to be a kind of antagonistic interaction between cells which serve adjacent regions of the retina

Other Interactions. The amacrine cells do show a transient response more nearly like that of a typical nerve cell, but they appear to respond with a transient at onset and offset of illumination, rather than continuously The ganglion cells are the first cells which show repetitive spike discharge, the frequency of which is related to the amplitude of stimulation Amacrine cells may have some role in adaptation and almost certainly are involved in the complex processing of visual information in the retina of lower vertebrates (Lettvin et al, 1959)

Insofar as Dowling and his colleagues have been able to make recordings from individual cells of the retina in other vertebrate species higher than *Necturus*, they have not found contradictory results Nonetheless, it would be

premature to generalize from their finding to the mammalian retina or to the primate retina without some qualification As discussed earlier, the nature of interconnections among the various cell types of the retina differs significantly even among mammals

RECEPTIVE FIELD ORGANIZATION OF THE RETINA

Long before the technical problems associated with intracellular recording in the retina had been overcome, it was possible to record the activity of individual ganglion cells with extracellular electrodes (Kuffler, 1952) In a typical procedure, the electrode is inserted into the retina until activity which represents the discharge of a single cell is detected The activity may be spontaneous, or some search technique involving a flashing light or a moving pattern may be employed Once a cell response is identified, the electrode is maintained stationary and an exploration of the way in which response of the cell changes through stimulation of the retina in various regions may be undertaken When explorations are made with a small test spot, it is found that the retinal region which must be stimulated to induce any activity or change in activity at the cell is roughly circular It is divided between a central zone and a surrounding zone which are antagonistic in their effects Stimulation of the central zone may cause either excitation or inhibition For cells which are excited by stimulation of their central region, the stimulation of the surround causes inhibition When stimulation of the central region is inhibiting, stimulation of the surrounding region will be exciting (Fig 8 86)

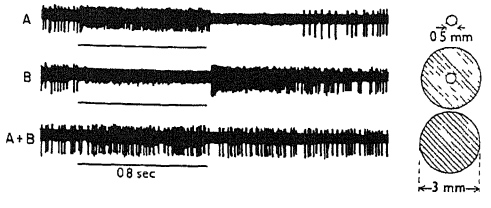

Fig 8 86 The spike discharge response of a ganglion cell of the retina of a cat to various forms of light stimulation An appropriately centered small spot of stimulation gives rise to a high frequency discharge Stimulation of an annular region around the central spot results in inhibition Stimulation of the entire region both center and surround results in a level of discharge slightly less than that evoked by the center spot alone (Brown and Wiesel 1959)

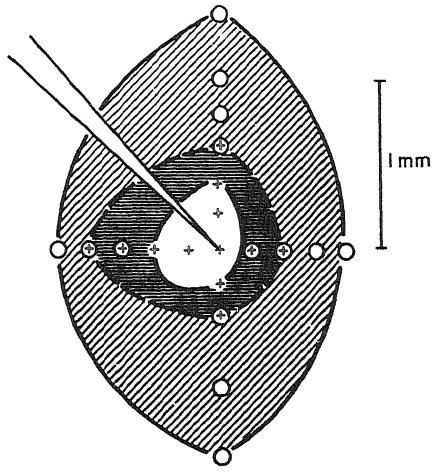

Fig 8 87 Diagram of a receptive field in the retina of the cat The contours are based on the response of a microelectrode which is presumed to be in contact with a single ganglion cell When an exploring light spot illuminates the region labeled + *on* discharges occur when regions labeled O *off* discharges occur There is an intermediate region marked ⊕ in which both *on* and *off* discharges are recorded (From Kuffler 1953)

This kind of receptive field organization is found in the cat (Fig 8 87), in the monkey, and presumably is the type of receptive field organization which exists in man This organization is also found in other animals such as the rabbit, the squirrel, the frog and the pigeon, but other more complex organizations are also present (Lettvin, et al 1959) These more complex organizations are apparently associated with a greater significance of the role of the amacrine cell in retinal interaction

There is some evidence that the organization of the receptive field may change when the eye is dark adapted (Studies of receptive field organization are typically performed in a light-adapted preparation) Barlow and co-workers (1957) have reported that the antagonistic surrounding element of the receptive field drops out when the eye becomes dark adapted Their experiment has attracted considerable interest in connection with our efforts to understand the nature of the dark adaptation process To some extent at least, the increase in sensitivity of the dark-adapted eye must be attributed to an increased spatial summation capability Lateral inhibitory effects are not entirely compatible with spatial summation and the notion of a reorganization of the receptive field during dark adaptation which might favor summation is therefore attractive (Fig 8 88)

Just as the absence of lateral inhibition effects may render the eye more capable of spatial summation and hence increase its sensitivity at very low light levels, lateral inhibition at high light levels may be useful as a basis for enhancing the spatial resolution capacity of the eye Excitatory receptive field centers on the lighter side of a boundary between a light portion and dark portion of the retinal image such that the inhibitory surround is partially within a darker region will have a lesser total amount of light on the inhibitory surround than is true for other receptive fields of similar spatial size and organization which are all in the region of higher illumination In consequence, the ganglion cell associated with the receptive field center near the boundary with the darker region may be excited to a higher level of activity The effect may be to enhance the difference in excitation selectively in the region of boundaries (Fig 8 89)

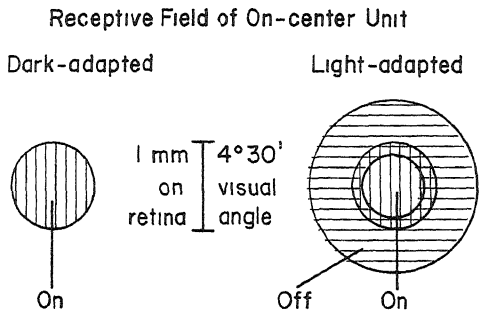

Fig 8 88 Suggested organization of the receptive field of an *on*-center unit in the retina of the dark- and light-adapted cat *On* or *off* responses are obtained when the stimulus falls in the correspondingly labeled regions of the field Locations of the limits of these regions are based on inferences from area threshold curves (Barlow Fitzhugh and Kuffler 1957)

Attempts have been made to devise precise quantitative models which will be descriptive of the role of inhibitory processes in the retina (Reichardt and MacGinitie, 1962) When such models adhere strictly to known principles of neuroanatomy and neurophysiology, involve constants which have values which are reasonable in biophysical or biochemical terms, and at the same time provide a good description of experimental results and possibly afford some prediction of what one may expect in experiments yet undone, then they may be considered as theoretical interpretations of what may actually be occurring in the nervous system Unfortunately, most such models fit only the data upon which they are based, require arbitrary constants to do so, and are of limited predictive value

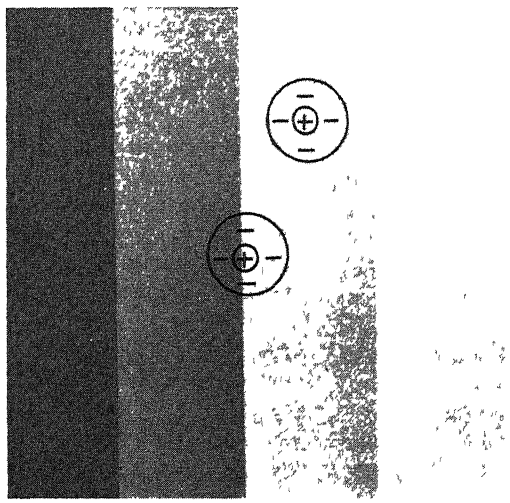

Fig 8 89 Border contrasts in a pattern of bands which increase in lightness from left to right The reflectance of each individual band is constant although bands appear lighter in the region of the left-hand boundary This may result from the lesser amount of stimulation of surrounding inhibitory regions of receptive fields in the vicinity of the boundary In the schematic illustration of receptive fields on the figure the ganglion cell stimulated by the field adjacent to the boundary will presumably fire at a rate higher than that stimulated by the field located near the center of the band

DIFFERENTIAL RETINAL RESPONSES TO STIMULUS WAVELENGTH

In animals with color vision, there must be some differentiation of responses to stimulating lights having different wavelength distributions Such differentiation must occur at the most peripheral point in the receptor system As noted above, cones are equipped with pigments having different absorption spectra and hence may respond differentially when the wavelength of the stimulus is changed It may be assumed that a different pattern of subsequent retinal events will follow when the light stimulus is changed from red to green, for example Unfortunately, most of the work which has been done on the differential responses of the retina to different wavelength distributions of the test stimulus has been done in the fish The color vision of the fish, although it must have arisen via a quite different evolutionary path from that of the human, is very similar to the color vision of man As illustrated in the first figure of Chapter 1, studies of the response of the fish retina to different wavelength distributions of the stimulus have shown that graded potentials may be obtained with a different polarity depending upon the spectral character of the stimulus (Svaetichen and MacNichol, 1958) Such graded potentials may have arisen in bipolar cells or horizontal cells It seems doubtful that the primary receptor itself could respond directly with either hyperpolarization or depolarization although this kind of response is not a physical impossibility. There are photoconductive materials which respond differentially to light of different wavelength distributions It seems probable that bipolar cells, such as those illustrated in Figure 8 85, may respond in one direction when light of an appropriate wavelength illuminates the receptor element to which they are directly connected and in a different direction when a nearby receptor having a different photopigment is stimulated by light of a different wavelength with a resulting activity in some horizontal cell which results in a response of the bipolar cell in the opposite direction

One study of the ganglion cells of the monkey indicates that there are indeed differential responses of these cells to changes in the distribution of the wavelength of the stimulus (Gouras, 1968) This work is preliminary, however, and does not provide a basis for our understanding of the detailed nature of the retinal connections which are involved in color discrimination

THE LATERAL GENICULATE BODY

The results of microelectrode studies of receptive fields for single cells of the lateral geniculate body of the cat (Hubel and Wiesel, 1961) are very similar to results obtained by electrode recording from the ganglion cell layer of the retina or the optic nerve Receptive fields show a concentric organization with antagonistic center and surround characteristics The variability of response at the level of the lateral geniculate body is considerably greater than is the case at the retina, however Activity within the reticular formation probably influences activity of the lateral geniculate body (Hubel, 1960, Arden and Soderberg, 1961) In addition, there is some evidence for cortical influence on activity of the lateral geniculate body (Widén and Ajmone-Marson, 1961) and anatomical bases for such influence have been confirmed Although binocular interaction within the lateral geniculate body has been reported in the cat (Bishop and Davis, 1953), there is no substantial evidence for physiological interaction of inputs from the two eyes at the level of the lateral geniculate body in primates In spite of the large number of experiments which have been performed on the neural activity of the lateral geniculate body, possible differential functions of the different layers remain obscure There is both convergence and divergence of connections from cells in the retina to cells in the lateral geniculate body and one result would appear to be an increase in spatial contrast at the lateral geniculate body (Hubel and Wiesel, 1961)

Color Coding The most extensive electrophysiological studies of the color vision process in primates have been done on the lateral geniculate body (DeValois, 1965) Individual cells have been found which respond by increased activity to all wavelengths of light and which have a spectral response characteristic similar to that of the visual system as a whole (Fig. 8 57) Other cells, called color-opponent cells, have been found which show increased levels of activity for stimulation in one wavelength region and a suppression of the resting level of activity in another wavelength region Some

cells may be excited by relatively long wavelengths of light and inhibited by middle wavelengths These are characterized as "red-on, green-off " Other cells may be characterized as 'green-on, red-off " Still other cells have been found which may be characterized as "yellow-on, blue-off" and "blue-on, yellow-off" (Fig 8 90) The precise nature of the response of these cells depends upon the condition of adaptation of the eye

Some effort at determining the spatial organization of the receptive fields of color differentiating cells has already been made by Wiesel and Hubel (1966) They have reported three main types of cells (Fig 8 91), the first of which must be involved in both spatial and color discriminations, the second of which is apparently involved primarily in color discrimination and the third of which is apparently specialized primarily for a role in spatial discrimination

The first class of cells has either an excitatory or inhibitory center with an opposing surround Center and surround have different spectral response properties Receptive field sizes are relatively small, many well under 1° in diameter The on-center types are smaller than the off-center types and all tend to be smaller when their receptive fields are located closer to the fovea In order of frequency, they have been found with "red-on" centers and "green-off" surrounds, "red-off" centers and "green-on" surrounds, "green-on" centers and "red-off" surrounds, "green-off" centers and "red-on" surrounds, and "blue-on" centers and "green-off" surrounds Other possible color combinations were not found

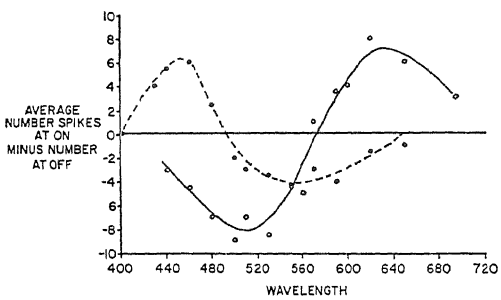

Fig 8 90 Difference between average number of spike discharges at stimulus onset and average number of spike discharges at stimulus offset as a function of wavelength (nm) of the stimulus for each of two single neural units in the lateral geniculate body of the monkey The results illustrated with solid circles and a dashed line show a maximum *on* response in the blue region and a maximum *off* response in the yellow region Results presented with open circles and a solid line indicate a maximum *off* response in the green region and a maximum *on* response in the red region of the spectrum (DeValois 1960)

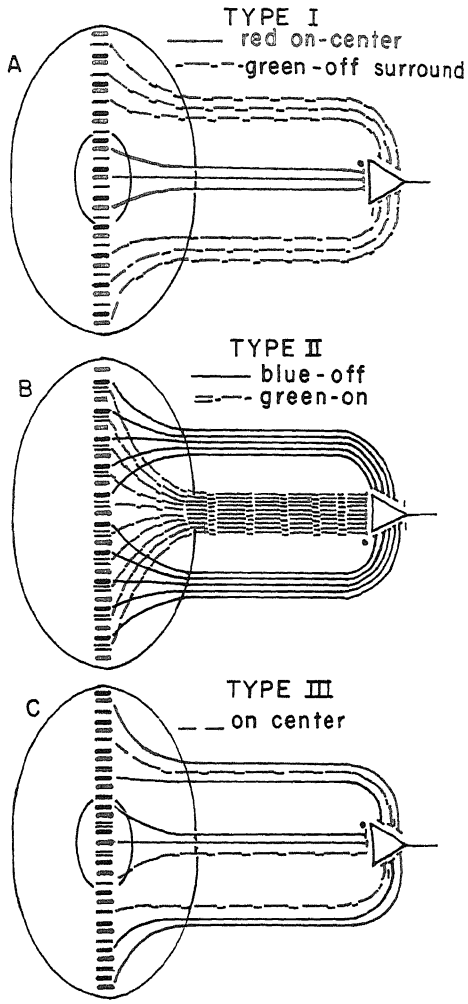

Fig 8 91 Nature of units showing a selective response to wavelength of stimulus in the lateral geniculate body (Wiesel and Hubel 1966)

The second type of cell, a small minority of the total, showed no differential center-surround organization Opposing responses dependent upon the wavelength of stimulation were found over the entire receptive field, sometimes "green-on, blue-off" and sometimes "green-off, blue-on " A very few were found with red and green connections These receptive fields also tended to be less than 1° in diameter

The third type of cell was found to have a concentric "on" or "off" center and opposing surround but no spectral differentiation between center and surround Still another type of cell was found in the ventral layer of the LGN with a concentric "on" center and a very large "off" surround The spectral response properties of these cells tend to be displaced toward the long wavelength end of the spectrum When both center and surround were stimulated, the response characteristic of the surround tended to prevail The opposite is true for concentrically organized receptive fields of the retina and most of those reported heretofore in the LGN

THE ACTIVITY OF SINGLE CELLS OF THE CORTEX

Receptive Fields. Unit activity of cortical cells has been studied by a large number of investigators, but the work of Hubel and Wiesel (1962 to 1965) has probably attracted the most attention In most of their work, these investigators have found almost exclusively elongated receptive fields associated with single cells when a spot of light was employed for mapping of the fields Receptive field organizations are shown in Figure 8 92 for comparison with two receptive fields found in the lateral geniculate body The linear organization of the cortical receptive fields found in Area 17 as illustrated in the figure has been characterized as "simple " In Area 17 and more often in Areas 18 and 19, receptive field organizations are found of a more complex sort These also respond optimally to stimulation by a line element, either a white line on a dark field or the converse

For both simple or complex cells, it is important that the orientation of the line correspond to the optimum for the receptive field The complex cells respond to stimulation which is relatively independent of the precise position of the stimulus, however Orientation remains critical but the line element may be displaced laterally Higher order hyper-complex cells have been recorded for which the length of a line element stimulus may be important as well as other geometric characteristics of the stimulus

Presumably, ganglion cells, the receptive fields of which represent linear arrays on the retina, each project to individual cells of the

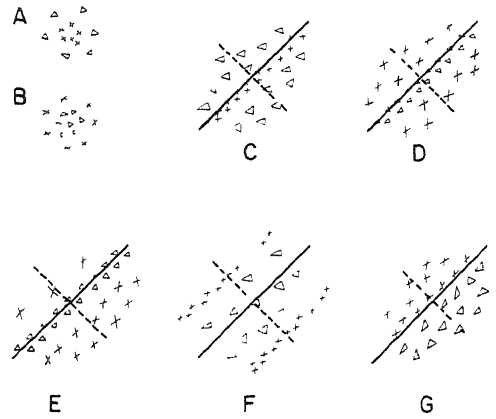

Fig. 8 92 Receptive fields of simple cells in the cortex of the cat compared with the circular organization of receptive fields of the lateral geniculate body *A on-center geniculate receptive field B off center geniculate receptive field C to G* various arrangements of simple cortical receptive fields Areas indicated by × produce an *on* response with retinal stimulation areas indicated by △ are inhibited by retinal stimulation and discharge when the stimulus is terminated A solid line shows the axis of orientation of the receptive fields Each kind of arrangement is found in all orientations (Hubel and Wiesel 1962)

lateral geniculate body, all of which in turn converge upon a single cell in the striate cortex Such single cells then show the kind of organization illustrated in Figure 8 92 Sets of these simple cells which represent parallel line elements must then converge upon single cells which show the complex field organization Higher orders of complexity are associated with higher orders of convergence of cortical cells This kind of arrangement is illustrated in Figure 8 93 Some of the work of Hubel and Wiesel has been confirmed by other investigators (Baumgartner, Brown, and Schulz, 1965, Spinelli and Barrett, 1969) but these other investigators have also found some cells in the cortex with circular receptive field organizations

As they reported earlier for the cat (1962), Hubel and Wiesel (1968) have reported columnar organization of cells in the monkey cortex Columns of cells oriented perpendicularly to the cortical surface contain cells which all have similar receptive field orientations An independent and overlapping set of somewhat larger columns contains cells which tend to respond to one or the other eye There is some indication that cells may also be grouped on the basis of their responses to movement

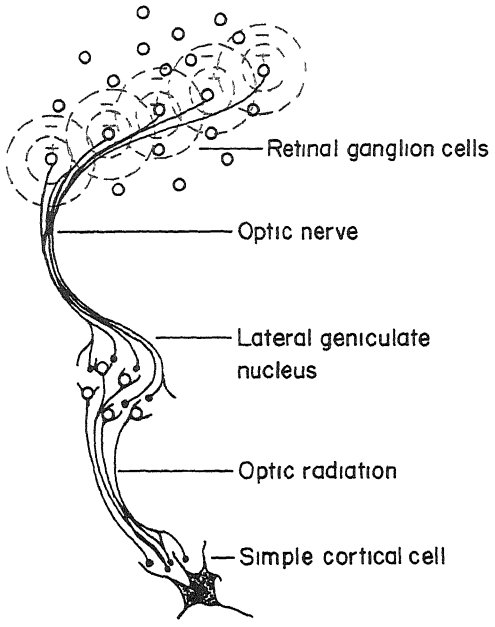

Fig 8 93 Connections from retinal ganglion cells through cells of the lateral geniculate body to the single cells of the cortex which respond to line element stimulation of the retina

Some cells in both cat and monkey show responses which are specific to the direction of motion of the visual stimulus In monkeys, receptive fields tend to be smaller and sensitivity to stimulus pattern orientation more specific than in the cat

In addition to the columnar organizations, there appears to be organization in depth in the visual cortex In the monkey, complex and hypercomplex cells which are driven by either eye are found in the outer layers (II and part of III) In middle layers (III and IV) simple cells predominate In layer IV, units lacking in orientation specificity have been found in the cat, as reported by Baumgartner and co-workers (1965) and Spinelli and Barrett (1969), but these units could conceivably be the axons of geniculate cells In the monkey, most of the cells of layer IV respond only to stimulation of one eye The cells of layers V and VI, like those in layers II and the upper part of III, have mostly complex and hypercomplex fields and are binocularly driven There are relatively few binocularly activated cells in Area 17 of the monkey Binocularly activated cells are common in this area in the cat, on the other hand.

Color Coding. Only a small percentage of the cells of the cortex of the monkey which have been examined for their possible color coding characteristics have proven to be responsive to differences in the spectral character of the stimulating light (Hubel and Wiesel, 1968) Some of these were found to have concentric field organization unlike any found in the lateral geniculate body Only 25% of the simple cells and 7% of the complex and hypercomplex cells of the cortex gave responses specific to color of the stimulus The nature of color coding in the cortex has been studied by other investigators, but there is no clear agreement as to its nature (Motokowa, Taira, and Okuda, 1962, Gouras, 1970)

Binocular Coding. As indicated earlier, the first significant interaction of neural activity from the two eyes probably occurs in the cortex Recently, receptive fields have been found in the cortex which are driven more effectively by stimulation of both eyes than by stimulation of either eye alone The locations of the receptive fields on the retinas of the two eyes are not always in the same relation to the area centralis of the cat, however, or in the same relation to the fovea in the monkey The field of one eye may be slightly further away from the center than that of the other Thus, when the retinal center is being stimulated by a given point in space, some other point or object in space must be either further away or closer to the animal than the point fixated in order to stimulate this particular kind of receptive field equally well in both eyes This is due to the disparity of image location in the two eyes for any objects in the visual field which are at a different depth than objects which stimulate corresponding points (Barlow, Blakemore, and Pettigrew, 1967) When the eyes of the cat are immobilized, an optimum distance can be found for a line element stimulus in the proper orientation which will give rise to maximum response Presumably, this distance is such that for the orientation of the two eyes the stimulus object will be imaged on both of the receptive field locations for the particular cell from which recordings are being made An illustration of the typical disparity found, on the average, is presented in Figure 8 94 for both the vertical and the horizontal direction It is evident that the range of disparity is much greater for the horizontal than for the vertical direction When the head of the animal is in a normal erect position, the two

eyes are displaced horizontally, and therefore, disparities resulting from differences in depth of objects in the visual world are horizontal In the monkey, unlike the cat, cells which respond optimally when both eyes are stimulated have only been found in Area 18 About half of the cells in Area 18 require stimulation of both eyes for the elicitation of more than a weak response For some of these, the receptive fields of the two eyes correspond geometrically, for others there is a disparity in positions of the two fields (Hubel and Wiesel, 1970)

Work of this kind suggests that specific cortical cells which respond to objects in the visual world at specific distances relative to the point of regard of the organism may be involved in the process of binocular depth discrimination They could also be involved in the control of vergence movements of the eyes associated with changes in depth of fixation

DEVELOPMENTAL ASPECTS OF CORTICAL PROCESSES

In recent years, there has been considerable interest in the relation of visual experience to the development of the corticoneural processes which subserve vision Experiments have been performed on cats in which several different

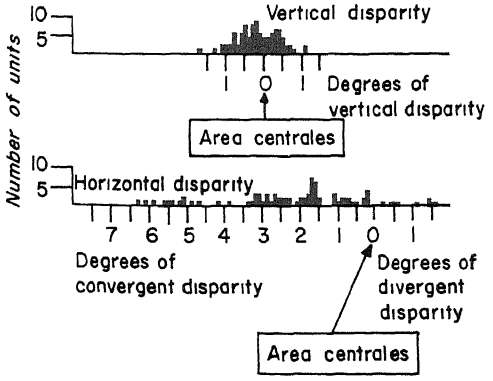

Fig 8 94 Histograms of horizontal and vertical disparities of the centers of 87 binocularly stimulated units in seven cats Estimated positions of the two areas centrales were assigned zero disparity Horizontal angular separation of the two receptive field centers less than that of the areas centrales were taken to indicate convergent disparity greater angular separations were taken to indicate divergent disparity Units with convergent disparity are excited optimally by objects located closer to the animal than its point of fixation The reverse is true for units with divergent disparity (Barlow, Blakemore, and Pettigrew, 1967)

procedures have been employed (Ganz, 1971) If both eyes are covered at birth or sutured shut and left that way for the first 3 months of life, there is a gross impairment of vision Subsequent electrophysiological studies indicate that fewer cortical cells with elongated receptive field organizations are found Whereas in the normal animal, virtually all cortical cells are responsive to visual stimulation, more than a third of the cells in the binocularly deprived animal are unresponsive (Wiesel and Hubel, 1965) Those cells which do respond show a proportion responsive to stimulation of either eye which is approximately the same as that in the normal animal

If only one eye is kept closed for 3 months, the effect is very much more severe for the deprived eye than is the case with binocular deprivation Wiesel and Hubel (1965) found that only 7% of cortical cells from which they recorded would respond to stimulation of the deprived eye

Neurons in the visual cortex of kittens 8 to 16 days of age respond to complex visual stimuli such as edges and contours in a way which is qualitatively similar to the response found in normal adult animals (Hubel and Wiesel, 1963) This suggests that the effect of deprivation is some kind of degenerative process rather than a failure of development in the absence of stimulation Clearly, the degeneration, whatever its nature, is more severe when an alternative mechanism, i e , an uncovered eye, is available

Behavioral studies with cats which have been visually deprived confirm the neurophysiological studies Binocularly deprived animals have difficulty in making form discriminations which are relatively easy for the normal animal For an animal which has been monocularly deprived for the first three months, such discriminations may be impossible with the deprived eye Brightness discrimination, color discrimination in primates, and gross form discriminations may show little or no effect of binocular visual deprivation (Riesen, 1958) Impairment of the deprived eye is noted after protracted monocular deprivation, however, for brightness discrimination and gross form discrimination The impairment would appear to be fairly specific to finer kinds of pattern vision after binocular deprivation

In the normal animal a high percentage of the cortical cells examined may be stimulated

via either eye Both eyes may participate in excitation of a large majority of the cells If, at birth, the ocular muscles are severed so that conjugate eye movements are impossible, a different result is found The elongated receptive fields of the cortex can be detected, but the majority of them are stimulated either by one eye or the other, not by both eyes (Hubel and Wiesel, 1965)

The shorter the duration of the interval for which eyes are closed, the less marked are impairment effects on vision There does appear to be a critical duration which, in the case of the cat, is approximately the first three months after birth Extensions of this work with the monkey indicate that the most critical period for deprivation of vision is in the first 6 weeks of life, but that the critical period lasts for at least the first year of life

CONTROL OF EYE MOVEMENTS

Movements of the eyes are extremely complex Four distinct types of movement may be distinguished As we look about us, without moving our heads, at stationary objects within the visual field, our eyes move in their sockets in a conjugate fashion so that both are always directed toward the same point of regard Such eye movements are called saccades They are extremely rapid and may reach a peak velocity of 400°/sec (Robinson, 1968) The reaction time for a saccadic movement is approximately 200 msec These movements are classified as voluntary, but they may be initiated involuntarily by peripheral visual stimulation They may also result from a lateral auditory stimulus Neural control of these movements appears to be coded in terms of eye position rather than eye movement (Robinson, 1970, Schiller, 1970)

A second class of eye movement is the smooth pursuit movement This is only possible when the eye is tracking a moving target All other voluntary movements are saccadic When some object moves within the visual field, it is possible for the eye to pursue it smoothly Such movements may be voluntary or involuntary If a repetitive pattern is moved continuously in front of the eyes, particularly in a horizontal direction, it is virtually impossible to prevent pursuit movements by the eyes Such movements are referred to as the *optokinetic reflex* Control of pursuit movements as contrasted with saccadic movements would appear to be based on velocity rather than position of the stimulus The eyes are capable of following a moving target with reasonable accuracy up to approximately 30°/sec Smooth pursuit movements up to velocities as high as 100°/sec are possible but not in maintained synchrony with a moving target (Robinson, 1968)

Both saccadic movements and pursuit movements are conjugate in that the two eyes move together as the point of regard is shifted in a frontal plane On the other hand, when fixation shifts from one object to an object which is located at a different depth, vergence movements occur If we look from a near to a far object, the eyes must diverge in order to maintain fixation With transition of the point of fixation to an object much closer, the movements will include convergence

The visual world appears to be remarkably stable in view of the mobility of our heads Compensatory eye movements which provide correction for movements of the head, as long as these are not excessive, are controlled by the semicircular canals of the vestibular system These represent a fourth class of eye movements When movements of the head are extreme, such as is the case when the body is rotated continuously about a vertical axis passing through the head, eye movements resulting from stimulation of the semicircular canals may be maladaptive Oculovestibular nystagmus occurs with a relatively slow motion of the eyes in the direction opposite that of rotation and a fast motion in the direction of rotation The slow phase is apparently controlled by the vestibular mechanism and is compensatory in nature When the eyes reach their anatomical limit, the fast phase of nystagmus serves to "reset" them for a subsequent repetition of the slow phase Slow and fast phases of motion alternate as long as the eye is exposed to continuing angular acceleration The slow phase is initiated by the vestibular mechanism while the fast phase is apparently under control of the same system which is involved in saccadic movement While smooth pursuit movements can follow stimuli at a rate of up to only 30°/sec , the vestibular system can compensate for angular rotations of greater than 300°/sec This would seem more than adequate for most rotations of the head, but it is not sufficient for such extreme rates of rotation as those which may be undergone by a

figure skater executing a spin Rates of over a 1000°/sec have been measured in these circumstances

Independence of the neural mechanisms involved in smooth pursuit movements and saccadic movements is illustrated by the differences in appropriate visual stimuli for their elicitation (Rashbass, 1961) The separation of the systems is further supported by the fact that they are influenced differentially by the use of barbiturates (Rashbass and Russell, 1961) These drugs act on the smooth pursuit system before any influence can be detected on the saccadic system Similarly, vergence eye movements have been demonstrated to be distinct from conjugate movements (Rashbass and Westheimer, 1961) They, too, show differential sensitivity to barbiturates (Westheimer and Rashbass, 1961)

Each of the four systems for eye movement control converges upon the motor nuclei that innervate the extraocular muscles with resulting movements of the eyeball (Fig 8 95) Movements induced via the various systems are additive at this final common path

CENTRAL NERVOUS SYSTEM INVOLVEMENT IN EYE MOVEMENTS

The Saccadic System. Saccadic movements of the eyes may be evoked by stimulation of Area 8 of the cortex, the frontal eye fields (Fig 8 96) Conjugate contralateral saccades are induced by a brief stimulus train in the unanaesthetized monkey (Robinson and Fuchs, 1969) These movements cannot be distinguished from the animal's spontaneous saccades Extent and direction of the motion appears to depend upon the region of the frontal eye fields stimulated Once threshold for the effect has been exceeded, the movements occur in an all or none fashion ranging from 2° to 60° in extent with amplitude as well as direction dependent upon stimulus location Experimental investigations of the result of artificial stimulation of the frontal eye fields would appear to indicate that they are adequate for the control of all saccadic movement of the eyes Fibers from the area descend in the cortical bulbar tract to the pontine reticular formation

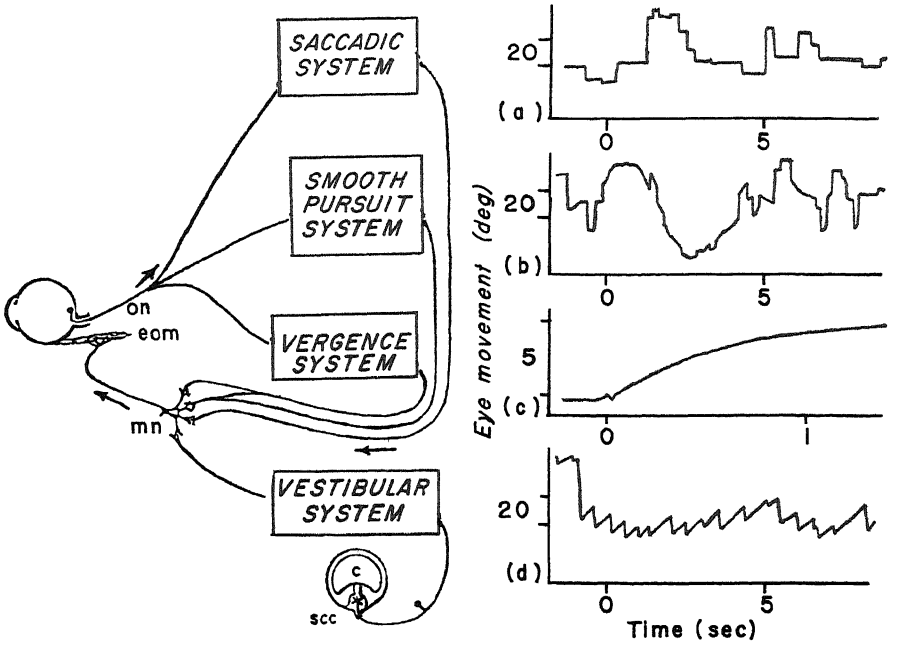

Fig 8 95 The primate eye movement control system The types of eye movements controlled by the saccadic system are illustrated at a the smooth pursuit system at b the vergence system at c and the vestibular system at d Each system converges on the motor nuclei (mn) which innervate the extraocular muscles (eom) and move the eyeball Optic nerve on cupula c semicircular canal scc (Robinson 1968)

Unfortunately, the attractive conclusion that saccadic movements are initiated by frontal eye fields is rendered difficult by the fact that recordings from single units in this area indicate that such units fire *during* the occurence of saccades rather than in advance of their occurrence (Bizzi, 1968, Bizzi and Schiller, 1970)

The Smooth Pursuit System. Smooth pursuit movements are believed to depend upon information from Areas 17, 18, and 19 of the visual cortex (Fig 8 96), as well as from the superior colliculi Cells in these regions may provide information as to the direction and velocity of image movement on the retina (Robinson, 1968) The tegmental region is probably also involved Velocity information from the cortex presumably joins information from the superior colliculi and the tegmental and pretectal regions in the corticotectal tract The role of the superior colliculi is somewhat in doubt, and it has been demonstrated that eye movements may occur in the absence of these structures (Pasik and Pasik, 1964) Goal directed movements of the eyes, i e , changes of fixation to specific points in the visual field, may involve the superior colliculus Stimulation of specific points in the superior colliculus has been shown to result in eye movements of a highly specific sort (Apter, 1946)

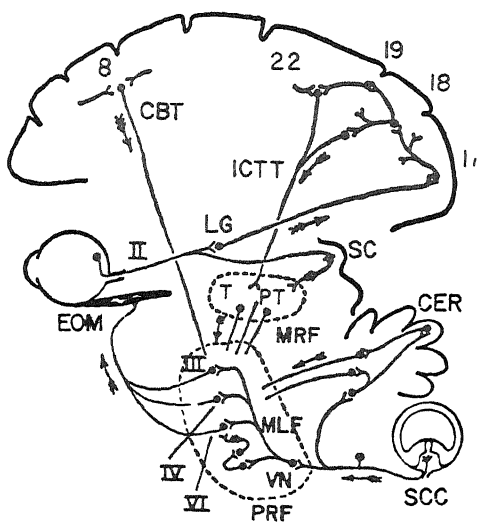

Fig 8 96 Major oculomotor pathways in the central nervous system CBT corticobulbar tract CER cerebellum EOM extraocular muscles ICTT internal corticotectal tract LG lateral geniculate body MLF medial longitudinal fasciculus MRF mesencephalic reticular formation, PRF pontine reticular formation PT, pretectal nuclei SC superior colliculi SCC semicircular canals T, tegmentum VN vestibular nuclei, II optic nerve, III IV VI, oculomotor trochlear and abducens nuclei and cranial nerves, 17 18 19 22 Brodmann s areas of occipital and parietal visual and association areas, 8 Brodmann's premotor area in the frontal lobes (Robinson 1968)

Vergence Movements. When cortical Areas 19 and 22 are stimulated electrically in the lightly anesthetized monkey, vergence movements result Presumably, information in these cortical areas is transmitted via the internal corticotectal tract to the brain stem (Robinson, 1968)

The Vestibular System. Pathways involved in the mediation of ocular response to vestibular stimulation are perhaps the best known of all those involved in eye movement control Signals from vestibular nuceli are relayed along the medial longitudinal fasiculus to the appropriate motor nuclei and thence to the extraocular muscles Diverging pathways extend to the pontine reticular formation and the cerebellum as well As mentioned above, the fast phase of vestibular nystagmus may be under control of those pathways which mediate saccadic movements In any case, the fast phase depends upon the brainstem between the vestibular and oculomotor nuclei

Robinson (1968) has pointed out that the mesencephalic and pontine reticular formation are extremely important in eye movement control All four of the oculomotor subsystems illustrated in Figure 8 96 convey information to these formations, and it may be here that the final integration of activity in each of these systems is accomplished prior to the transmission of signals to the final common path

BASIC VISUAL FUNCTIONS

The rich visual experience which our eyes afford us may be understood in terms of several fundamental response properties of the visual system One of the most primitive is the ability of the eye to discriminate differences in brightness This is a fundamental ability and may have been the primary function of evolutionary precursors of the complex vertebrate eye The vertebrate eye has the capability of differential brightness discrimination over the area of the retina This spatial discrimination capability is perhaps the most interesting and most important characteristic of the visual system Its utilization depends in large measure on the ability of the visual system to make temporal discriminations as well Very

rapid changes in the character of stimulation of a given point on the retina or of the whole pattern of stimulation of the retina may be followed without difficulty The interval in which the eye is capable of integrating energy from external sources of light represents a useful compromise The integrating capacity permits the utilization of lower flux levels for seeing On the other hand, if integration occurred over too long a period, the effect would be to blur the visual world as effects of one stimulus merged with those of another The integration interval is matched nicely with the rates of eye movement and the average duration of fixation on a given point in the visual world

The range of illuminations over which the eye is capable of functioning is extremely great From the lowest threshold luminance to which the eye can respond to the maximum luminance which can be viewed without damage to the eye, there is a range of over 1,000,000,000 to 1 Nevertheless, the eye does not function efficiently immediately when the illumination level is changed Although it is capable of adapting fairly rapidly from low levels to high levels, it requires a fairly long time interval to adapt from relatively high levels of illumination down to the lowest levels which can be detected In the latter case, a half an hour or longer may be required

Another fundamental capability of the normal human eye is the differential discrimination of light based on its wavelength composition This is a function which involves the cones and relatively high levels of illumination

Finally, the eye has the ability to make spatial resolutions in depth as well as in the projections on the plane of the retina Of the variety of cues for the discrimination of depth, one of the most important is the disparity of the elements which are illuminated by corresponding parts of images on the two retinas by reason of the fact that the two eyes are separated in space as they view the three-dimensional world in which we live

Functions Related to Brightness

BRIGHTNESS DISCRIMINATION

Innumerable experiments have been performed to ascertain the relations among the amount of light required for detection and the luminance of the background, the location of the light in the visual field, the size of its image on the retina, its temporal duration, and its spectral characteristic and the spectral characteristic of any background illumination which may be present as well as the condition of adaptation of the eye (Graham, 1965a) When the purpose is to determine the minimum luminance which can be detected either against a dark background or an illuminated background, such experiments are classified as brightness discrimination experiments (Brown and Mueller, 1965) For the observer, the discrimination is always relative to the spatial or the temporal dimension A region of the visual field is seen as brighter than its surround or a region of the visual field (perhaps the entire visual field) is observed to become brighter at some point in time relative to its previous appearance Such experiments may also be carried out with a decrement of luminance rather than an increment when a sustained adapting level of illumination is employed (e g , Herrick, 1956)

The experiment reported earlier on the absolute minimum amount of light energy which can be detected (Hecht, et al , 1942) represents an extreme on the continuum of brightness discrimination experiments As the eye is adapted to higher and higher levels of illumination, the luminance of an increment which can just be detected against such a background adaptation level increases in accordance with the function represented in Figure 8 97 It is evident that the required increment in retinal illumination increases at an increasing rate as the background luminance is increased Presumably, there is some level of background illumination sufficiently high that no additional increment can be discriminated against it Such a background level would completely saturate the visual system

The data in Figure 8 97 represent the test intensity required for the detection of a light against a background adapting intensity for a human observer and in the retina of the monkey Data from the retina of the monkey are based on a selected criterion response level of the late receptor potential (Brown, 1968), this is recorded with a tiny electrode inserted into the retina at an appropriate depth to provide an index of the activities of the receptors themselves The similarity between the two functions is rather striking It suggests that the form of the intensity discrimination response

function may be determined in the receptors themselves It should be recognized, however, that the late receptor potential as recorded represents the activity of many receptors It is undoubtedly also influenced by interactions which occur as a result of connections of the horizontal cells The function which represents the data for the monkey retina in Figure 8 97 must therefore be recognized as representative of the retina but perhaps not exclusively of the receptors themselves When the eye is adapted to a higher luminance, a significantly higher test stimulus is required for detection For any given level of adaptation the nature of the response at the retina is remarkably similar to that at other adapting luminances In Figure 8 98, the response in terms of percentage of the maximum late receptor potential is plotted as a function of the test intensity for each of six conditions of adaptation The functions, with the exception of that for dark adaptation, are remarkably similar and are simply shifted to higher ranges of test intensity with increase in the level of the adapting intensity (Boynton and Whitten, 1970) The range of response of the system thus remains approximately the same for any condition of adaptation, but as the adapting conditions are elevated, there is an expansion of the range of luminances over which gradations in response may be obtained The "gain" of the system is thus reduced as higher levels of background luminance are encountered and this occurs in the early processes which take place within the retina itself This kind of process is undoubtedly involved in the ability of the eye to function over an intensity range of greater than 10^9 1

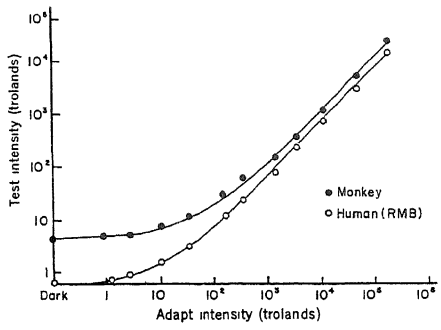

Fig 8 97 Log of threshold retinal illumination (trolands) as a function of the adapting level The solid points represent a 10 μv criterion response level of the late receptor potential of a monkey The open circles are based on human foveal thresholds measured with the same apparatus (Boynton and Whitten 1970)

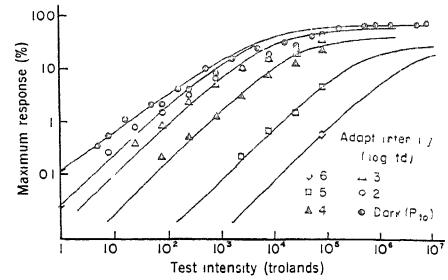

Fig 8 98 Late receptor potential amplitude (percent of maximum) as a function of test flash intensity for each of five adaptation intensities and for dark adaptation Average values for six monkeys (Boynton and Whittel 1970)

DARK ADAPTATION

There are important changes which occur within the visual system when illumination is reduced from daylight levels to very low levels before it is possible for even the crude low luminance or "scotopic" vision to become optimum The process of "dark adaptation" requires a half an hour or longer after an abrupt transition from a high illumination surrounding to one of relative darkness (Bartlett, 1965b) In Figure 8 99, the minimum amount of light which can just be detected is represented on the ordinate and time in the dark is represented on the abscissa The ordinate axis is plotted on a logarithmic scale, thus greatly amplifying the lower portion of this relationship For a period of from 8 to 12 min after a high luminance adapting field has been removed, the threshold value at first reduces rapidly and then the rate of reduction in threshold is slowed, reaching a minimum at about 10 min A little later there is a subsequent additional reduction in threshold which again occurs at a decreasing rate and approaches a minimum at some time after 30 min in the dark

For various reasons, the higher threshold portion of the curve in Figure 8 99 has been associated with the cones and the lower threshold portion has been associated with rods In the first place, when a small test stimulus is employed which is restricted to the fovea, two branches are not obtained In the second place, if a red test light is used for which the rods are no more sensitive than the cones, the second branch of the curve does not appear, even though the test light may be presented to a region of the retina which is rich in rods If a subject in a dark adaptation experi-

ment is asked to identify the color of a test flash, he is able to do so during most of the time for the first 8 or 10 min of dark adaptation, corresponding to the initial segment of the curve in Figure 8 99, but is unable to do so unless the test light is restricted to extremely long wavelengths at later times during dark adaptation Thus, color discrimination is approximately associated with the "cone" portion of the curve and the inability to discriminate color is associated with the "rod" portion of the curve

It was believed for many years that the time course of dark adaptation could be understood in terms of the time required for regeneration of the photopigments of the visual receptors which are bleached by any high level adapting light (Hecht, 1937) The time course of dark adaptation certainly is associated with the regeneration of photopigments, but the level of threshold cannot be explained directly in terms of the concentration of photopigment present or the quantum catching capability of the retinal pigments It has been demonstrated fairly conclusively (Rushton, 1962) that the threshold is still very much elevated even after 90% of the photosensitive material has been regenerated following bleaching of substantial percentages of the photopigment

The time course of dark adaptation, as suggested above, is greatly influenced by the testing procedures employed This is illustrated in Figure 8 100, which shows three different dark adaptation curves obtained with each of two test field sizes in two different retinal regions (Arden and Weale, 1954) When a small test field is confined to the foveal center of the eye, a single function is obtained which shows the reduction in threshold at a decreasing rate with time If the same small test field is presented at a location 8° away from the foveal center, a curve of a different sort is obtained There is an initial function showing reduction in threshold at a decreasing rate followed by a subsequent similar function which carries threshold down to a lower level which,

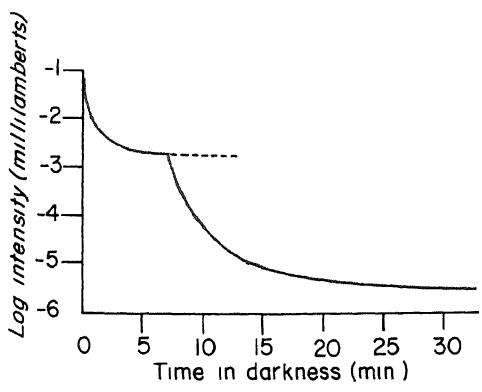

Fig 8 99 The time course of reduction in a light detection threshold during dark adaptation The initial branch of the curve is associated with photopic vision and is attributed to cone function The later branch is often called the scotopic branch and is associated with rod function

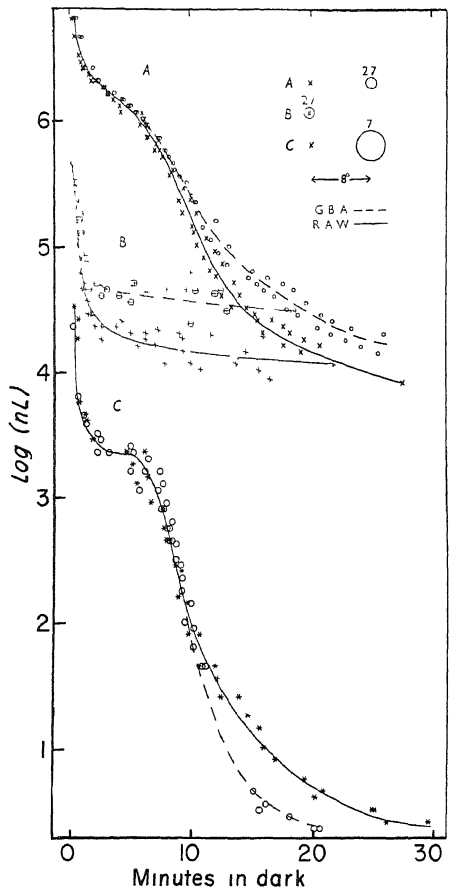

Fig 8 100 Dark adaptation curves measured for two test field areas and two retinal locations Results are presented for each of two subjects for each of the three conditions The upper functions represent a very small test spot centered on the fovea or located 8° from the fovea The lower functions represent a large test area centered 8° from the fovea The larger drop as compared on a logarithmic axis of the late branch of the function for the large test area with the smaller test area in the periphery indicates a larger relative change in threshold with the large test area This suggests a spatial summation effect which is developing during the time interval represented by the function (Arden and Weale 1954)

in fact, corresponds fairly closely with the final level reached in the fovea If a substantially larger test field is employed centered on a point 8° away from the fovea, again a curve of two branches is obtained, but the function is displaced downward The initial branch is very similar to that obtained with a small test field although displaced downward on the threshold axis The later branch, however, is much steeper than that obtained with the small test field Here, as in Figure 8 99, threshold is presented on a logarithmic axis The significance of this is that a given distance along the threshold axis represents relative amount of change quite independent of the location along the axis Thus, there is a relatively much greater amount of change in threshold in the same time interval for the later branch of the dark adaptation curve when a large test field is employed The function can thus hardly be described as exclusively dependent upon the regeneration of photopigment Relative change in threshold would be uninfluenced by such a variable as test field size if the sole determinant of threshold were the relative amount of photopigment available The much steeper "rod" branch for the larger test field in the periphery can most probably be explained in terms of some sort of increased capability of the eye to summate stimulus energy over area during dark adaptation There are other evidences for such a change in addition to the data presented in Figure 8 100 Direct tests of the ability of the eye to summate stimulus energy over area show that this can be accomplished to a greater degree in the dark-adapted as compared with the light-adapted state (Bartlett, 1965b)

The data of Figures 8 99 and 8 100 show that when the eye is placed in darkness it becomes more sensitive by a factor of 1,000,000 1 or greater as it remains in darkness for up to 30 min or longer This has been attributed, as suggested above, to increased ability of the retina to summate energy over area There are, in fact, three mechanisms involved, but the increased areal summation capability is probably the most important First, when the eye is placed in darkness, there is an increase in the size of the pupil The pupil may expand in diameter from a minimum of little more than 2 mm to a maximum of something in excess of 8 mm. This represents a range of change in area by a factor of 16 1 To that extent, the eye has become capable of gathering light more effectively from any given external light source, but the increase in effectiveness is hardly sufficient to explain the tremendous range of change which accompanies dark adaptation Secondly, the bleached photopigments do regenerate, but as Rushton has shown, the logarithm of change in threshold is more nearly proportional to the change in concentration of photosensitive material than is the change in threshold itself The tremendous range of change during adaptation is most readily explained in terms of changes in retinal organization which permit increased summation of energy over area and time as well as to some mechanism which increases the responsiveness or "gain" of the system at very low levels of illumination (see below) Such a mechanism is implied by the parallel functions of Figure 8 98 From these it is clear that much smaller ranges of change in stimulus energy result in the same range of change in response in the retina when the eye is adapted to very low luminances There is a variety of theories as to the precise mechanisms involved (Barlow, 1964, Dowling, 1967, 1970)

Barlow has suggested that the mechanism of dark adaptation may involve the gradual subsiding of a retinal noise level which is the result of photic stimulation According to his interpretation, following termination of a light stimulus, the receptors themselves maintain some level of activity which is reduced only gradually Dowling has shown that the B-wave of the electroretinogram shows a relation to increased background luminance which is similar to that shown by the activity of retinal ganglion cells The ganglion cells in turn are excited by the bipolar cells either directly or via amacrine cells Dowling therefore speculated that the adaptation process may involve some kind of inhibitory feedback of amacrine cells on bipolar cells which serves to reduce the gain of the system at high levels of illumination More recently (1970) he has shown that the B-wave of the electroretinogram as measured in a gross retinal response is most nearly duplicated by the response of glial cells when the response characteristics of individual components in the retinal complex are compared

It should be evident that the precise mechanisms which underlie the adaptability of the visual system to such a broad range of condi-

tions of illumination are as yet unknown It has been clearly demonstrated, however, that with increasing dark adaptation there is increased spatial and temporal summation at the retinal level These changes permit more efficient utilization of small quantities of energy They occur at the expense of both spatial and temporal resolving power of the eye as discussed further, below

There are certain misconceptions concerning the effect on vision of adaptation to very low luminances The increased temporal and spatial summation capabilities permit detection and utilization of low light levels They do not preclude fine spatial and temporal resolution if sufficient light is presented to the eye when it is in a dark-adapted state That is, the dark-adapted eye is capable of just as high a level of spatial or temporal acuity as is the light-adapted eye, given sufficient luminance to work with Of course, if the necessary luminance remains available for any length of time, then the state of adaptation is changed from one of dark adaptation to some level of light adaptation Nonetheless, fine spatial detail can be discriminated quite well in a very brief flash of sufficient luminance presented to the dark-adapted eye (Brown et al , 1953) This is illustrated in Figure 8 101, which shows the time course of dark adaptation measured with the presentation of brief test flashes for a variety of visual tasks If the eye is required merely to detect the presence of a light, then the lowest curve is obtained If the eye is required to identify the orientation of a line pattern in the test flash, then the progressively higher curves are obtained with the finest line pattern resulting in the highest of the curves It is evident that for a line pattern which represents a sufficiently small image size on the retina, there is no late rod branch of the dark adaptation curve Clearly, the rods are unable to make a contribution in a visual task of this sort and the function is performed by the cones The dark adaptation of the eye, however, does not interfere with the identification of fine patterns It might be supposed that the increased sensitivity of the rod receptors which are themselves incapable of resolving fine detail might somehow interfere with the resolu-

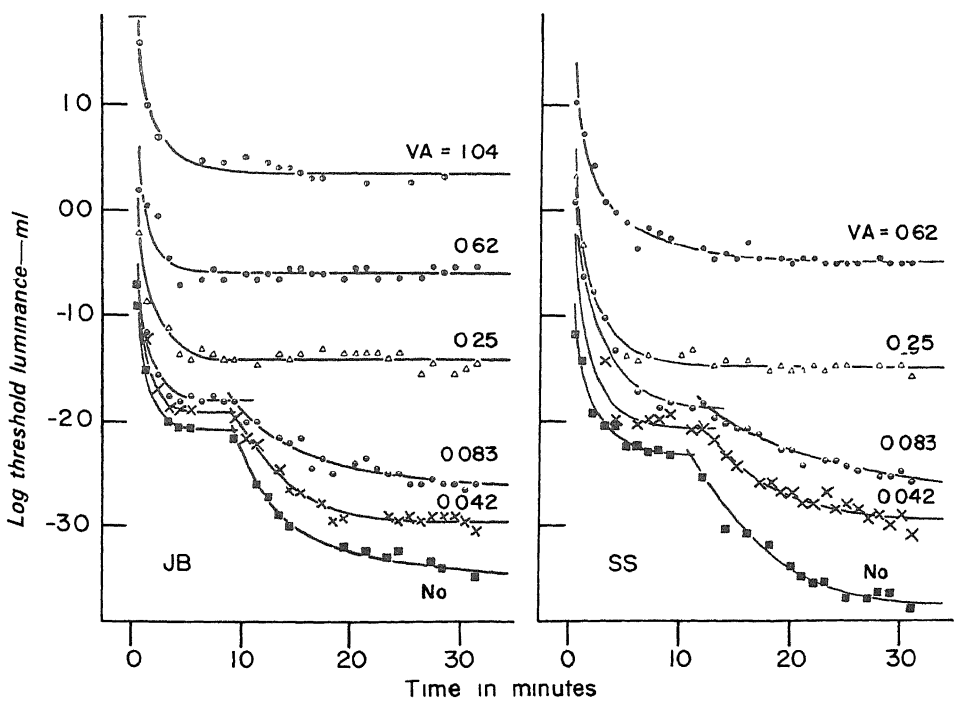

Fig 8 101 Luminance thresholds for the resolution of acuity gratings during dark adaptation for each of two observers The number beside each curve refers to the level of acuity (reciprocal of the visual angle subtended by a grating line) The bottom curve represents simple detection of light with no grating present (Brown et al 1953)

tion of such fine detail by the cones This would be reflected by an elevation in the later portion of the highest curves in Figure 8 101, but no such elevation is observed (Brown et al , 1969)

LIGHT ADAPTATION

Just as the eye adjusts when the visual environment is darkened, so does it also adjust when the environment is made brighter The nature of the response is similar, as illustrated in Figure 8 98, when it is considered on a log log plot, but, as mentioned earlier, this implies a reduction in the gain of the system A given amount of change in response requires a proportionately greater change in the level of stimulation when the adapting level is raised We have seen that it may require more than 30 min for the eye to achieve maximum sensitivity in darkness after it has been exposed to a bright adapting light The time course of adaptation to a lighter environment is usually much more rapid Under most circumstances, light adaptation is complete in from 3 to 5 min , and the eye adjusts to a relatively steady state condition of responsiveness within that time

The time course of light adaptation has been measured in a variety of ways Early measurements were performed by exposing the eye to an adapting light after it had been completely dark adapted and then determining its sensitivity by turning off the adapting light and quickly presenting a test light (Wald and Clark, 1937) Thus, a given adapting luminance would be selected, the dark-adapted eye would then be exposed to this luminance for a short duration, the luminance would be extinguished and at some fixed time very soon after it was extinguished a test flash would be presented for the measurement of threshold This process would have to be repeated time and again with variation in the level of test flash in order to determine a threshold, and again and again for greater and greater durations of light adaptation The results of such studies indicated that with increased duration of exposure to an adapting light, there is an increase in the threshold for detection of subsequent test light as adapting exposures increase up to 3 to 5 min and sometimes much longer The process has been attributed to a decrease in the available photosensitive materials of the retina which continues in time until the rate of regeneration of photosensitive materials sustains a relatively constant and, of course, somewhat lower concentration of photopigments corresponding to the higher level of light adaptation employed

There is more to light adaptation than a change in the average concentration of photosensitive materials, however Light adaptation may be measured in a somewhat different fashion which gives very much different results In the alternative method, a test flash is presented against the light adapting field which is left on The test is thus one of the ability of the eye to discriminate an increment in brightness against the adapting luminance The method is somewhat easier in that test flashes may be presented at various intervals during the entire time course of the light adaptation process On subsequent exposures to the adapting light, slightly higher luminances may be used at a given time when the observer was unable to detect the test flash and lower luminances may be employed when the test flash was visible By repeating the process, it is possible to obtain a measure of threshold for the increment, or test light as a function of duration of the adapting light (Crawford, 1947, Baker, 1949) The results of an experiment performed in this way are presented in Figure 8 102 The function is not a simple one and requires some explanation In the first place, it is important to point out that the experimenter has begun by presenting the test flash in advance of the time at which the light adapting field is turned on This is done in order to provide a baseline level of response in the dark-adapted state A very interesting result of this procedure is the finding that the threshold for detection of the test light begins to be elevated when the test light is presented about 50 msec prior to the presentation of the adapting light Test flash threshold increases rapidly to a maximum at about the time the adapting light is turned on and then reduces in value for a brief interval prior to rising again and reaching a final level which is typical of the specific adapting luminance employed after about 10 min of light adaptation This result may at first seem mysterious in that it appears that the visual system is somehow able to anticipate the occurrence of a stimulus which has not yet been presented This apparent anachronism can readily be understood when we consider that the temporal dimension

in Figure 8 102 is determined by timing devices in the laboratory On the other hand, the actual detection of the test flash is determined within the nervous system Clearly, within the nervous system, influences on a test flash are occurring as the result of the presentation of an adapting light which illuminates the retina as much as 50 msec after the presentation of the test flash The significant factor is that the detection of a flash does not occur at the retina The detection on the part of a conscious observer, as evidenced by his reporting that he sees the flash, probably occurs somewhere in the cortex The relatively low luminance of the test flash initiates a series of events which occupy a finite time interval prior to any detection and that time interval is longer than the time interval required for effects of the adapting flash to influence the same point in the nervous system The latter influence serves to elevate the measured threshold for the test flash

The initial presentation of an adapting light obviously has a significant, albeit transient, effect on sensitivity to a test light This effect is attributed to neural events in the retina Abrupt elevation of retinal illumination probably results in a level of neural activity considerably in excess of that which corresponds to the state of affairs after the adapting light has been on for some time Thus, the system cannot handle increment information as efficiently immediately after exposure to an adapting light as it can after the light has been on for a time The slower rise of threshold for the test light which follows the initial rapid elevation and subsequent decline is attributed to the more gradual change in photochemical balance within the retina

If dark adaptation experiments are performed with a test flash which is presented against the adapting field prior to the beginning of dark adaptation a result similar to that reported above for the initial stage of light adaptation is found to occur (Baker, 1953) There is an elevation in threshold for the test flash which must be attributed to the abrupt change in the level of illumination of the retina with a consequent neural effect which temporarily reduces the ability of the system to handle other additional information This phenomenon is illustrated in Figure 8 103

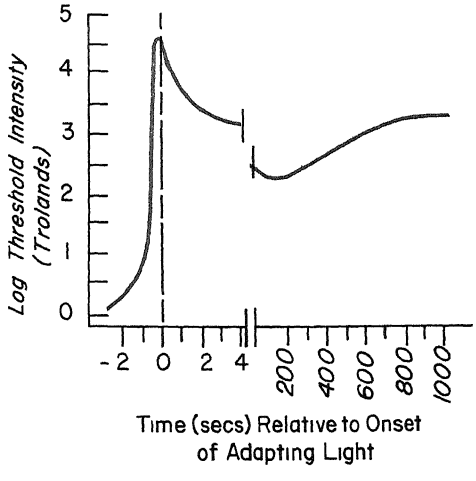

Fig 8 102 The time course of light adaptation as measured by an increment threshold technique Test flash thresholds are measured beginning at a time in advance of the actual presentation of the adapting light and continuing out to approximately 15 min (A hypothetical reconstruction based on the data of Crawford 1947 and Baker 1949)

Discriminations Related to Space or Time

SPATIAL RESOLUTION OF THE VISUAL SYSTEM

As mentioned earlier, one of the most important functions of vision is to provide information as to the relative location and identity of objects in the visual world The retina is extended in space and receives information which differs over its surface in correspondence to the way in which light from objects in the visual world differs spatially There are millions of individual receptor cells distributed over the retinal surface Images of objects in the visual world are distributed over arrays of these cells and the cells then somehow transmit information which the central nervous system is capable of employing for identification of the objects To the conscious observer, there is no complex processing of information required at the conscious level, he immediately apprehends the fact that an object is present and its identy. What he "sees" is for him the "real object" and not some coded neurological process which he must strive to decode

One of the puzzling things about this process is the fact that the visual image quality for the normal observer is better than one might pre-

dict If the aberrations of the optical elements of the eye and the size of the receptor cells are considered, the clarity of vision seems better than it should be Actually, interaction processes within the retina which have been considered above tend to sharpen the process of spatial discrimination and there is not a simple spatial discrimination system based on a point to point correspondence between differences in the level of stimulation of adjacent receptors in the retina and differences in level of excitation of corresponding neurons somewhere higher in the nervous system

Visual Acuity In the case of vision, the term *acuity* is reserved to refer to spatial resolution capability Visual acuity is formally defined as the reciprocal of the minimum visual angle in minutes subtended at the eye by an object in space which can be resolved by the visual system Visual acuity is not an invariant quantity for a given eye or even under a given level of illumination, it depends importantly upon the way in which it is measured

The simplest form of visual acuity is the so-called *minimum detectable* visual acuity. This

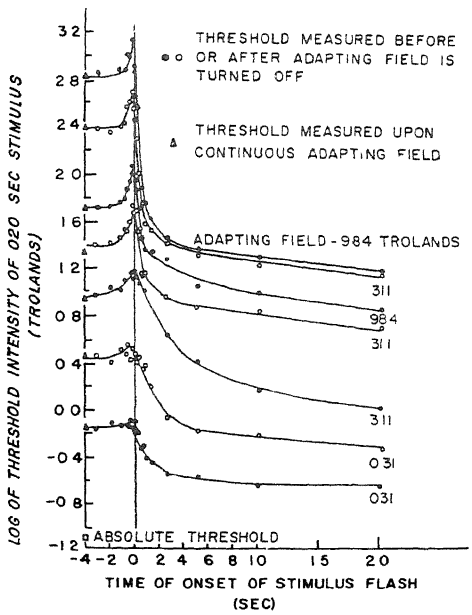

Fig 8 103 Early dark adaptation at 5° from the fovea The adapting field is turned off at time 0 Test flash threshold measurements begin 400 msec prior to the termination of the adapting light and are continued out to 2 sec after termination of the adapting light (From Baker, 1963)

is the discrimination of a small dark spot against a lighter background, or a dark line against a contrasting background Under ideal conditions, the finest line which can be resolved subtends a visual angle of less than 1 sec of arc This represents a visual acuity by the definition given above of greater than 60 The diameter of a dark spot against a lighter background must be somewhat greater then the width of a dark line in order to be discriminated

It is meaningless to attempt to associate a visual acuity value with a light spot or a light line against a dark background Detectability of such a spot or line depends entirely upon the relative luminous flux coming from the line or spot as compared to the background Easily detectable stars are so far away that the visual angles which they subtend at the eye are effectively zero There is sufficient light emanating from them, however, that they can readily be perceived If visual acuity were associated with them by the above definition, it would be infinite in value, hence the concept is meaningless under these circumstances

Another form of visual acuity which is somewhat more complex is sometimes referred to as the *minimum separable* visual acuity This refers to the ability of the eye to discriminate a separation between two points of stimulation This might be referred to two dark spots against a lighter background, or to two light spots against a dark background In this case, it is perfectly valid to consider light against dark and the identification of a separation between two light spots is clearly dependent upon spatial discrimination

Visual acuity measurements made clinically may depend upon a test of the minimum separable threshold The Landolt ring is a commonly used target on charts for the measurement of acuity (Fig 8 104*B*) The gap in the ring is positioned at random from one ring to the next on a given chart and the patient must identify the location of the gap The smallest ring size for which the gap can be correctly located determines the visual acuity with this test For the normal observer, the width of the gap subtends a visual angle of approximately 1 min of arc at the standard measuring distance of 20 ft Normal visual acuity for such a target is therefore *one* It is more often expressed in relation to the distance at which it can be correctly detected for a given observer in relation

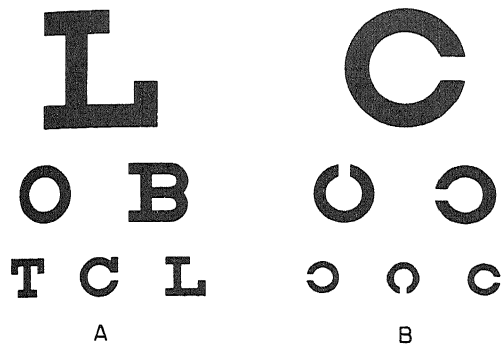

Fig 8 104 *A* Representative letters as used in a Snellen chart for the testing of visual acuity The lines and serifs of the letters are one fifth the height or width of the entire letter *B* Landolt ring test symbols The thickness of the line and the width of the gap are both one-fifth of the outer diameter of the ring (Riggs 1965b)

to a normal population Thus, an acuity of 20/200 implies that a given individual can resolve a test figure at a distance of 20 ft which the normal observer could resolve at 200 ft This represents a severe defect A visual acuity of 20/10 indicates that an observer can resolve a test pattern at 20 ft which the normal observer must view at a distance of 10 ft in order to resolve it

When visual acuity is tested with Snellen letter charts (Fig 8 104*A*), the procedure is very much the same The sizes of those elements which permit discrimination of the letters determine their visibility and visual acuity is calculated from the sizes of these elements for those letters which can just be resolved at the normal distance of 20 ft Again, a visual acuity of one, corresponding to a visual angle subtended by elements of detail of approximately 1 min of arc, is the norm Acuity is expressed as the distance at which the patient can identify the letters in a given line relative to the distance at which a "normal" observer can discriminate the same letters

Visual acuity is sometimes measured with a grating test pattern Such a pattern consists of parallel lines and spaces with lines equal in width to the spaces between them The grating pattern may illuminate a circular patch and may be changed in orientation so that the lines are vertical, horizontal, or oblique The observer is required to identify their orientation One advantage of such a target pattern over individual letters is the fact that the relative illumination in the retinal image is always precisely the same Only the orientation of the lines is altered Here again, the normal value is very close to 1 min of arc for the angle subtended by the width of a single line or a single space at the eye

The level of visual acuity of which the eye is capable is very much limited by the level of illumination available The higher the level of illumination, the higher the visual acuity up to a limiting value for a particular type of target (Shlaer, 1937) In Figure 8 105, visual acuity is seen to increase monotonically with increase in the logarithm of retinal illuminance up to a limiting value Results are presented for one observer with a Landolt C as a target and for two observers with a grating as a target The curves are quite different for the two different targets Acuity begins to rise rapidly at a lower luminance for the grating, but the maximum level reached is higher for the Landolt C These results demonstrate a very important point Many of our indices of visual function, such as visual acuity, are highly dependent upon the specific measuring technique employed. It is incorrect to think of these indices as representative of some invariant quantity which is independent of the procedures employed in its measurement

There is a significant difference between the use of letters and the use of gratings or Landolt rings In the case of the latter two, the nature of the figure is known The task is one of identifying the location of a character of the

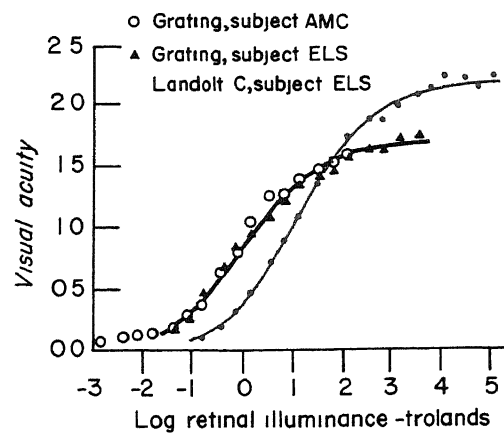

Fig 8 105 Visual acuity as a function of the logarithm of retinal illuminance in trolands for the resolution of a grating test object and the identification of the orientation of a Landolt ring test object Note the more rapid initial rise in acuity with increasing luminance for the grating but the higher final level of acuity for the Landolt ring (Shlaer 1937)

figure which the observer knows to be there at the outset In the case of a letter, the task is one of identification of a given test figure from among a number of possibilities, 26 if the entire alphabet is employed Identification when many possible alternatives exist is somewhat more difficult than the detection of a gap in a ring or orientation of the lines of a grating This is true, at least, when the number of alternatives is relatively large

Form Discrimination The ability of the visual system to aid in the identification of one object out of a number of alternative possibilities is perhaps even more interesting than the fineness of detail in the image on the retina which may be discriminated Obviously, the fineness of visual detail which can be discriminated is an important characteristic of the visual system in relation to its ability to discriminate form and recognize objects, but the way in which the visual system serves in the correct identification of a given letter is quite impressive, even when the size of the image of the letter on the retina is relatively large In this instance, we assume that the basis for discrimination is more dependent on cortical process than on the retinal process

We have already seen that there is not a point-to-point correspondence between individual cells of the retina and individual cells or groups of cells within the brain Rather, the nature of the signals transmitted by the million odd fibers of each optic tract is influenced by interactions between elements within the retina Numbers of receptive cells in the retina in a roughly circular array are included in the receptive field of a given ganglion cell Fibers from ganglion cells terminate on cells of the lateral geniculate body and the axonal processes from these terminate on cells of the cortex Many of the radiations from the geniculate body may terminate on a single cortical cell and there is evidence that the receptive fields in the retina associated with many of these radiation fibers are arrayed along straight lines There are thus cells within the cortex which respond essentially to line elements of stimulation within the retina It is possible that the discrimination of form, at least in its early cortical stages, depends upon the excitation of sets of such line element detector cells The matter is still one for speculation, but, as we have seen, there is evidence that connections to line element detector cells of the cortex which may exist in the newborn are somehow lost if one eye of a newborn kitten is occluded at birth and remains unstimulated by spatially varying patterns of light until beyond the 3rd month of life Along with this neurophysiological change, there is a degeneration of the visual process such that complex form can no longer ever be discriminated by the eye which was covered during the first 3 months of life

The discovery of cortical cells which respond to line elements of stimulation has prompted the study of a variety of effects which result from prolonged exposure of the human eye to line patterns of stimulation The threshold for detection of a grating pattern is influenced by pre-exposure to a grating pattern with its lines oriented in the same way If an observer looks fixedly at a vertical line pattern, it will have no effect on the subsequent threshold for detection of a horizontal line pattern but may elevate the luminance required for detection of a subsequently presented vertical line pattern or decrease the probability of correct identification of such a pattern at a given luminance level (Campbell and Kulikowski, 1966, Gilinsky, 1968) The effect can be observed with adaptation of one eye and testing of the other, suggesting that the site is in the cortex (Blakemore and Campbell, 1969, Gilinsky and Doherty, 1969)

Spatial Modulation Transfer Function. It has been found useful to specify the characteristics of optical systems in terms of a spatial modulation transfer function The modulation transfer function provides a statement of the range of sinusoidal frequencies which can be transmitted by the system and the extent to which amplitude at any given frequency is attenuated by the system A spatial modulation transfer function deals with sinusoidal waveforms distributed in space rather than in time Thus, a pattern of vertical bands which represent a sinusoidal variation in brightness from left to right at a given frequency and with a given amplitude of brightness difference between maximum and minimum values may be imaged by an optical system on some remote surface Measurements can then be made of the extent to which the amplitude of the brightness is reduced as a result of using the optical system Obviously, if the spatial frequency is very high, i e , the lines of the pattern are very fine and closely compressed, the

optical system may be unable to resolve the lines at all and the image will consist of homogeneous illumination At the other extreme, if the spatial frequency is too low, limitations on the spatial extent of the optical system or of the minimum rate of change in brightness over space which can be detected may prevent the transmission of any information about the low frequency change in brightness For systems where it is legitimate to consider complex spatial detail as composed of simple sinusoidal components in a given spatial dimension, such a specification may be very useful It will permit the prediction of the precision with which a given spatial distribution of illumination in an object may be rendered in the image by the optical system Systems for which this is true are said to be linear

The technique has been applied to the visual system, including those physiological processes which intervene between the retina and conscious discrimination of visual patterns as well as the optical elements of the eye It is not possible to measure the amplitude of some image of a line pattern in consciousness Therefore an alternative approach has been employed in which amplitude of the brightness difference between maximum and minimum points in the object is adjusted for threshold discrimination of the presence of the line pattern (Schade, 1956, Westheimer, 1960, DePalma and Lowry, 1962) It is assumed that at threshold the visual effect is a constant The greater the amplitude of the brightness in the pattern at which threshold is reached, the less sensitive is the system at that frequency Thus, the reciprocal of the amplitude of the brightness in the pattern which corresponds to threshold provides a measure of the sensitivity of the visual system Several functions which illustrate the reciprocal of amplitude at threshold for a range of spatial frequencies are presented in Figure 8 106 There is reasonable agreement among three of the four functions presented for the high frequency cut-off portion of the curves Unfortunately, with increased deviation from threshold the visual system can no longer legitimately be treated as a linear system and therefore the utility of the functions illustrated in Figure 8 106 is limited The overall luminance level of a pattern is an extremely important variable and the high frequency cut-off is reduced with a decrease in average luminance Reduced luminance is also

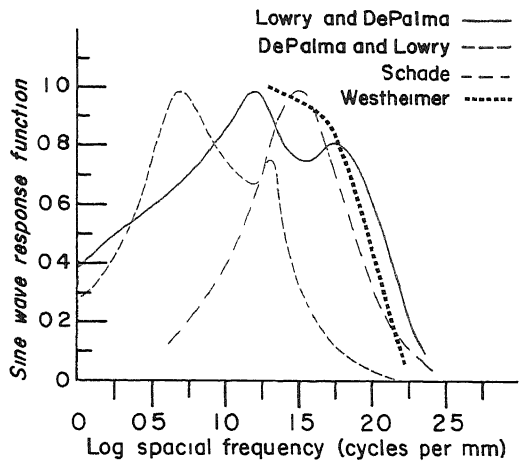

Fig 8 106 Normalized spatial modulation transfer functions for the visual system based on the data of four different experiments Sine-wave response function is related to the reciprocal of the modulation amplitude of the spatially varying sine-wave (Brown and Mueller 1965)

accompanied by adaptation of the eye to a lower level and also by a reduction in the maximum possible physical modulation amplitude of the stimulus

In spite of its limited value, the spatial modulation transfer function of the visual system has given rise to some interesting speculations As mentioned above, recent studies of the adaptation of the eye to line patterns of a given orientation have indicated that there is a selective elevation of threshold for lines of the same orientation subsequently viewed (Campbell and Kulikowski, 1966, Gilinsky, 1968) The effect is to some extent limited to patterns of comparable spatial frequency (Blakemore and Sutton, 1969) Adaptation to a grating pattern will elevate subsequent thresholds for resolution of grating patterns of similar orientations and frequencies which do not differ by more than an octave from the frequency of the adapting pattern (Blakemore and Campbell, 1969). This kind of adaptation is direction-sensitive and shows interocular transfer That is, if the adapting stimulus is presented to one eye, the subsequent effect may be observed with the other eye The directional sensitivity suggests the possibility that line element detectors in the cortex are involved and the interocular transfer capability of the effect provides further support for the conclusion that it is indeed cortical The possibility has been considered that there are specific neural systems for limited spatial fre-

quency ranges (Campbell, Nachmias, and Jukes, 1970)

So far, we have only begun to understand the basic visual functions which underlie such a process as complex as form discrimination It is now clear that aspects of visual information such as line elements and their orientation, motion (Baumgartner et al , 1964) and degree of visual disparity (Barlow et al , 1967) are "encoded" by specific cortical cells That is, certain cells seem to respond specifically and with a high degree of selectivity to such aspects of visual stimulation At the moment, such ideas are purely speculative, but it seems reasonable to suppose that higher order cells or assemblies of cells may become associated with such complex visual information as the identity of a face

Registration of Complex Spatial Information The capacity of the human observer to register information which is received visually seems to be almost beyond measure In a recent series of experiments (Haber, 1970) it was demonstrated that complex photographs numbering in the thousands, which had been seen for only a brief exposure, could later be identified with an accuracy well over 90% correct from among other very similar photographs which had never been seen before This is true even when the photographs seen earlier are projected with a left-to-right reversal of the image Somehow, cortical centers associated with the processing of visual information are able to register and identify an incredibly large number of extremely complex spatial distributions which are detected visually

There is some limited evidence (Luria, 1970) that visual information in the form of printed words may be remembered less efficiently The nature of cortical processing of language is involved with the reading of printed material and difficulties in reading may be associated with dysfunctions of cortical regions which play no role in the perception of visual information that is not associated with language Understanding of these phenomena is still very limited It is important to recognize, however, that there are many complications associated with the visual discrimination of form and visually presented information when we are dealing with situations only a little more complicated than those treated in fundamental studies of the spatial resolution capabilities of the visual system.

TEMPORAL DISCRIMINATION CAPABILITY OF THE VISUAL SYSTEM

Flicker Fusion Frequency. One of the oldest ways of studying temporal resolution capability of the eye has been the technique of presenting a series of flashes to the eye and determining the rate of flash presentation at which the stimulation appears to fuse and is seen as a steady light This is known as the *flicker-fusion frequency* or *critical frequency of fusion* (Brown, 1965b) The results of such a study are presented in Figure 8 107 This shows the critical frequency as a function of the logarithm of retinal illuminance (Hecht and Verrijp, 1933) Except at very high luminances, there is a tendency for the frequency of fusion to increase as retinal illuminance increases That is, the eye is better able to resolve temporal discontinuities with brighter stimuli Although it might seem more "reasonable" for a brighter light to be more persistent, this is obviously not the case We have already learned that the critical duration of the eye is shorter the higher the level of adaptation of the observer

The nearly linear relation over a range of approximately 4 log units between critical fusion frequency and the logarithm of retinal illuminance represents a relation which has been called the "Ferry-Porter Law " It is really not a law in that it does not always apply, but it is a reasonable approximation of the behavior of the visual system for flickering stimuli in a number of circumstances The two other curves in Figure 8 107 show critical fusion frequency for regions of the retina outside

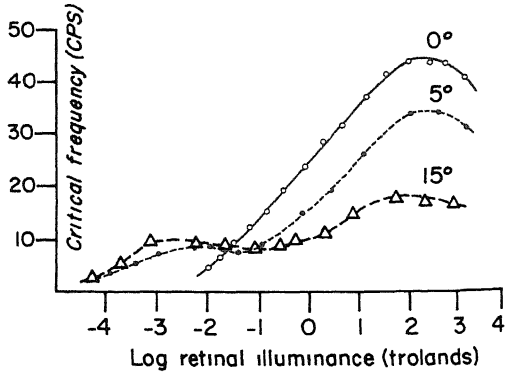

Fig 8 107 The relation between critical fusion frequency and log retinal illuminance for white light for each of three different retinal locations at the fovea and 5 and 15° above the fovea (Hecht and Verrijp 1933)

the fovea The initial branches of these two curves at 15° and 5° eccentricity are attributed to the function of rods The later branches are believed to reflect the function of peripheral cones They are lower by reason of the fact that peripheral cones are sparsely distributed This is presumed to be related to a decrease in their temporal resolution capability The decline of the critical fusion frequency at very high luminances may be attributed to some form of overloading of the retinal receptors Effects of adaptation, retinal location, binocular as opposed to monocular stimulation and spectral distribution of the stimulus all influence the critical fusion frequency There are a number of interactions among these variables but it is impossible to treat them in detail here Several comprehensive reviews of the subject are available (Brown, 1965b, Piéron, 1965)

Temporal Modulation Transfer Function. Just as a modulation transfer function has been investigated in the spatial domain, so has it been studied in the temporal domain of vision Instead of presenting to the eye a rectangular pulse of light which comes on and off abruptly and is interrupted by complete darkness between presentations, a light stimulus may be employed which varies in luminance sinusoidally with time Under these circumstances, it is possible to vary either the frequency of presentation of the stimulus or the amplitude of modulation of the stimulus The average luminance can be kept constant and modulation amplitude may be increased to a maximum of 100% for a sinusoidal stimulus As modulation amplitude is reduced, the stimulus approaches a steady light of unvarying luminance The results of a series of experiments for each of three retinal illuminations are presented in Figure 8 108 At all illuminations it is evident that as frequency is increased, the relative amplitude at which fusion occurs increases rapidly That is, the eye requires a higher amplitude of change in luminance in order to discriminate temporal discontinuity and thus may be said to show a reduction in its sensitivity to temporal variation The left-hand ordinate scale is the reciprocal of relative modulation amplitude At frequencies of over 50 or 60 Hz for the highest illumination employed, it is impossible to discriminate any flicker even at maximum modulation amplitude

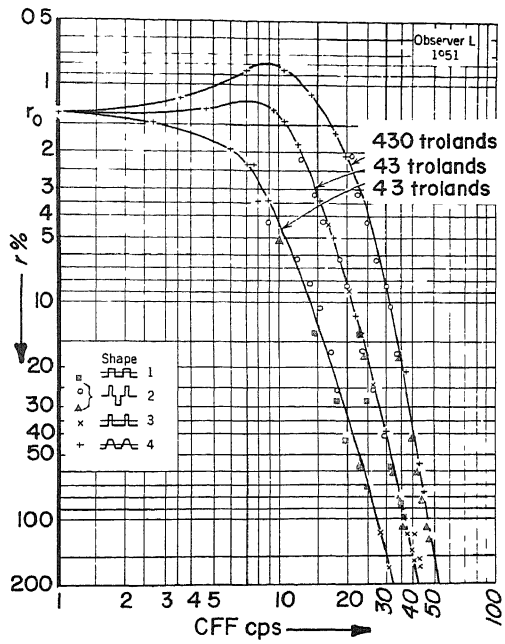

Fig 8 108 Modulation amplitude (r%) of the fundamental sinusoidal component at fusion as a function of frequency for each of four modulation wave forms or shapes The curves represent each of three retinal illuminances as labeled (de Lange 1958)

At the higher retinal illumination, there is the development of a kind of resonance effect A specific frequency appears to provide for maximum sensitivity and at higher and lower frequencies, higher modulation amplitudes are required The peaking or resonance phenomenon is emphasized when larger stimulus fields are employed such that border contrast effects are reduced (Kelly, 1961) For the conditions which obtained when these data were collected, the low frequency modulation amplitudes, expressed in relative terms, are the same for the three levels of retinal illumination investigated

The question must be raised as to the possible practical value of considering the modulation amplitude of a time-varying visual stimulus One very important conclusion which may be drawn is that high frequency variation cannot be discriminated At first, this seems obvious It has been known for a long time that intermittent stimuli are seen to fuse at frequencies which are usually below 100 Hz, with the frequency of fusion depending upon the level of illumination Figure 8 108 provides an additional kind of information, however Four different wave forms of the stimulus light were

employed in gathering these data Their forms are illustrated in the inset of the figure The actual plotted points in the figure represent only the fundamental sinusoidal component of the complex wave forms which were employed For a given average illumination, all of the data points fall on the same curve quite independent of the actual shape of the stimulus wave form The implication of this is that it is only the fundamental sinusoidal component which determines the relation between frequency and modulation amplitude for fusion at a given level of retinal illumination Apparently, the visual system acts as a filter and tends to eliminate the effects of higher order components Although there are special circumstances where this may not be true (Levinson, 1964, 1968), it is true in a sufficiently large number of circumstances to be of some usefulness in predicting the nature of response of the visual system to a time-varying, complex wave form

Perceptual Duration. Techniques other than determination of the time interval in which energy will summate (for the detection of threshold) and the measurement of critical frequency (for the fusion of flicker) have been employed in studying the temporal resolution capability of the eye One procedure uses two stimuli, one visual, and the other either visual or auditory When the second stimulus is an auditory signal, it is usually a click or other sound of very short duration The visual stimulus is presented and the observer's task is to adjust the time of occurrence of the auditory "marker" so that it seems to be synchronous in time with the onset of the visual stimulus In a subsequent series of settings, the observer adjusts the auditory marker so that it appears to correspond in time with the termination of the visual stimulus The difference in time between the termination setting and the setting which marks the beginning of the visual stimulus may be taken as a representation of the perceptual duration of the visual stimulus Studies of this sort indicate that the perception of a visual stimulus is of from 120 to 250 msec in duration (Sperling, 1960, 1967, Neisser, 1967, Haber and Standing 1970, Efron, 1970)

At fairly high levels of light adaptation, a black outlined figure on a white background has a perceptual duration of approximately 250 msec This was ascertained by adjusting the rate at which the black outlined target had to be presented repetitively in order to appear to be on continuously It was actually on for a duration of approximately 20 msec, but observers reported that it was seen continuously so long as it was presented within 250 msec of the preceding presentation on each successive presentation (Haber and Standing, 1969) When the observer is dark adapted and there is no steady background illumination, the "persistence" of a presentation of the same short duration and at the same luminance is increased to over 400 msec

In general, results of experiments of this sort indicate that a light flash of shorter than 250 msec presented to the light-adapted eye will appear to be of nearly 250 msec duration regardless of its duration For the dark-adapted eye, the apparent duration will be somewhat longer For longer light flashes, the apparent duration will conform fairly closely to the actual physical duration It is interesting to note that an interval of approximately 250 msec corresponds to the duration of individual fixations of the eye on a printed page Evidence indicates that an interval of from 200 to 250 msec is required for the processing of information derived from each visual fixation (Haber and Nathanson, 1969) This relatively long time interval of a quarter of a second as contrasted with a critical duration of the order of 0 01 sec in the light-adapted eye is most reasonably attributed to the involvement of cortical processes which must be invoked for the processing of complex information such as letters or words when these are presented sequentially at a fairly rapid rate The temporal resolution characteristics of the visual system are thus quite complex and include a brief limitation at the level of the retina for integration of energy and a more severe limitation which almost certainly involves higher centers in the brain for sequential discrimination of intelligent information Relatively long term temporal summation effects have been demonstrated when the observer's task has been the identification of specific symbols from a larger set of symbols such as letters or numbers (Haber and Hershenson, 1965) The fact that successive presentations of a symbol which shows summation may be presented alternately first to one eye and then to the other

provides clear evidence that such summation takes place at a cortical rather than a retinal level

Discrimination Based on Wavelength

COLOR VISION

The Trichromacy of Color Vision The eye is not nearly as good a discriminator of the wavelength or frequency of light as is the ear of the frequency of sound stimulation Within certain limits, any color sensation may be matched by the mixture of just three primaries if these are appropriately selected spectral lights The only stringent requirement in selecting primaries is that no two of them be complementary That is, that no two can be added together to produce a white or neutral sensation For practical reasons in the matching of colors associated with extreme wavelengths and having relatively high luminance, primaries are usually selected to include a red, a green, and a blue or violet element

Color Mixture. If any monochromatic light is represented in one-half of a bipartite field, it may be matched by the addition of three primary wavelengths in the other half of the bipartite field The relative amounts of three selected primaries required to match any monochromatic lights are illustrated in Figure 8 109 The individual luminances of the specific primaries selected have been adjusted so that when they are mixed in amounts proportional to their relative luminances, they will match a standard reference white

It is clear from Figure 8 109 that a negative amount of one of the three primaries is necessary in order to achieve a match at any wavelength below about 551 nm in the visible spectrum It is, of course, impossible to obtain a negative amount of light under any circumstances The negative values in Figure 8 109 therefore require some clarification In fact, precise matches of monochromatic lights cannot always be achieved by simple addition of all three of the primaries in the opposite side of a bipartite field It is sometimes necessary to add one of the primaries to the wavelength to be matched in order to achieve a perfect match between the two halves of the field

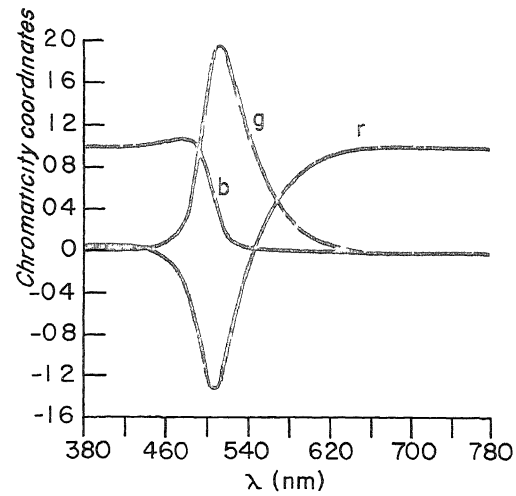

Fig 8 109 Chromaticity co-ordinates of spectrum colors for the standard observer Curves are based on spectrum primaries of 700 nm 546 1 nm and 435 8 nm The reference white is an equal-energy spectrum (Wintringham 1951)

The appearance of the wavelength to be matched is thus altered slightly when a small amount of one of the primaries is added to it It is accepted as a convention that when a given amount of a primary is added to the field to be matched, it is treated as a negative value in the overall addition process

Actually, quite good ranges of colors from violet to deep red may be achieved by simple additive mixture of primaries It is not possible to match all spectral colors without the subtractive technique described above, however

The fact that just three variables need be taken into account for color matching long ago gave rise to the speculation that the visual mechanism must involve three selective discrimination channels in the color vision system (Young, 1807) Such channels might involve each of three different pigments residing in each of three different classes of cones as was very early suggested We have seen above that this type of mechanism probably does, in fact, exist

In its simplest form of operation, such a system might encode information about color in terms of the relative responsiveness of each of the three systems for a given condition of stimulation That is to say, light of long wavelength would stimulate cones bearing red-ab-

sorbing pigments maximally, would stimulate cones with pigments absorbing in the green region of the spectrum slightly, and would hardly stimulate cones with pigments absorbing in the blue region of the spectrum at all The pattern of neural activity in the pathways subserving these three classes of cones would thus be characteristic for a given monochromatic wavelength of stimulation or for a selective distribution of stimulation over a range of wavelengths A theory of color vision based on this kind of reasoning was propounded by Helmholtz (1924) based on the earlier suggestions of Thomas Young (1807)

Opponents Processes. There are certain aspects of the function of the color vision process, however, which belie such a simple mechanism There appear to be inhibitory interactions between certain of the primary color discrimination mechanisms at stages central to the primary receptors When a red light is mixed with a bluish-green light, the combination tends to be achromatic if the components are appropriately selected Similarly, addition of a yellow light and a blue light may yield an achromatic product Individual wavelengths, which when mixed together tend to neutralize each other or produce a white stimulus, are said to be mixture complements It is as if they are stimulating elements within the color vision detecting system which work in opposition and hence tend to cancel out the effects of complementary stimuli when these are presented simultaneously

If the eye is exposed for a period of 5 or 10 sec to a bright red light and this is followed by a white field, the latter will appear greenish in hue If the original red stimulation was smaller in size than the subsequent white field, a green region will be seen against the white field corresponding in size to that of the original red stimulus. Such successive color contrast effects can also be seen dramatically following exposure to a green light which induces a red hue in a white field, or a yellow light which induces blue, or a blue light which induces yellow The precise after-image hue depends upon the wavelength distribution of the initial "inducing" stimulus As reported earlier, electrophysiological processes have been found at the level of the lateral geniculate body which indicate that on certain cells the effect of turning off a red stimulus is the same as the effect of turning on a green stimulus For other cells the reverse may be true Similar effects in individual cells are found for yellow and blue stimulus lights (DeValois, 1965)

If the region of the retina which permits identification of various hues associated with given wavelengths of stimulation is studied carefully, an interesting result is found Red and green may be identified out to a certain distance from the fovea which is very nearly the same for each of these colors On the other hand, wavelengths which typically elicit the response "yellow" or "blue" can be presented at a greater distance from the fovea and will evoke the characteristic color-naming response In a word, the color discrimination ability of the retina for yellow and blue extends out further into the periphery than is the case for red and green These relations are illustrated in Figure 8 110 Finally, if a small patch of color is surrounded by a neutral field and the reflectance of the neutral field is adjusted appropriately, the neutral field will appear tinged with a hue corresponding to the complement of the color patch This is known as simultaneous color contrast (Graham and Brown, 1965) It is attributed to spatial interaction effects which probably reside in the retina, but as yet there is only limited information as to what the nature of these interaction processes may be (Gouras, 1968)

COLOR BLINDNESS

The evidence favoring opponents processes that involve red and green as apparently having opposite effects, and yellow and blue as apparently having opposite effects, are lent further support by the nature of color blindness Although some color blindness is complete, most is not, in that most individuals who suffer from deficiency in color discrimination are able to discriminate some colors although not all Where three primaries are required for the normal observer, many of these color blind individuals require only two They are therefore called *dichromats* as opposed to *trichromats*, the term employed for the normal observer, or *monochromats*, the term applied to the completely color-blind. Dichromacy exists in four specific forms These include *protanopia*, *deuteranopia*, *tritanopia*, and *tetartanopia* (see below) The names applied to these forms of color vision serve only to discriminate them as four different types and have no other scien-

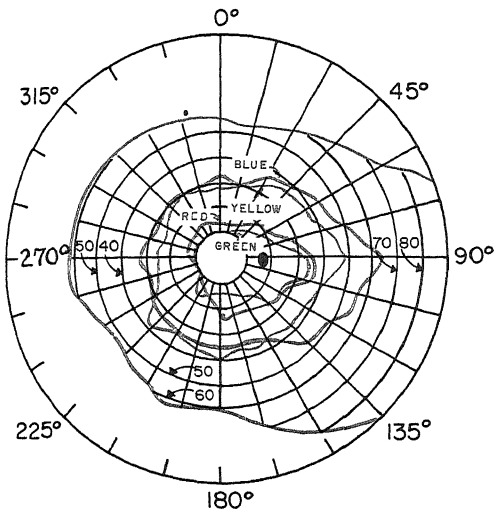

Fig 8 110 Retinal receptive fields in which red green blue yellow and achromatic lights can be detected Note that the zones in which color may be discriminated are smallest for red and green somewhat larger for yellow and blue and largest for the simple detection of light independent of color (Optical Society of America 1953)

tific significance Tritanopes are extremely rare and the status of the fourth type, tetartanopia, is unclear Its frequency of occurrence is sufficiently small that it need not be given serious consideration

Monochromats. There are individuals whose vision is entirely monochromatic, that is, they can match any spectral distribution with a single monochromatic light, provided they are permitted to adjust its luminance Any monochromatic wavelength will serve perfectly well Monochromats, sometimes called achromats, are for the most part found to lack normal cones The vision of these rod monochromats is scotopic and their luminosity function corresponds to that of the dark-adapted peripheral retina of the normal (Sloan, 1954) Visual acuity is low, high luminances are disturbing and there is chronic nystagmus A small percentage of monochromats apparently have one type of cone in addition to rods It has been suggested that these individuals may see in a single color under photopic conditions and in shades of gray under scotopic conditions If this is true, they probably should not be called achromats, although the unitary character of their photopic vision can hardly provide any useful chromatic information Cone-monochromats have been reported with a photopic peak sensitivity at 440 nm (Blackwell and Blackwell, 1957, 1961), suggesting the presence of "blue" cones, and with a peak of 545 nm There is some question as to whether the latter absorption peak represents the function of "green" cones (Pitt, 1944, Weale, 1953)

Dichromats. Both protanopes and deuteranopes tend to confuse reds and greens The colors which they perceive are all in shades of yellow and blue as these are seen by normals This conclusion is based on evidence from cases of monocular color blindness (Judd, 1948, Graham et al , 1961) In such individuals the appearance of various stimuli presented to the dichromatic eye may be matched in the normal eye and thus provide an indication of what the color-blind eye sees relative to normal color vision The color confusions of the tritanope involve yellows and blues Presumably, color blindness involves some deficiency in the mechanisms which contribute to the opponent processes of the normal observer

Extensive studies have been performed on the spectral response functions of color-blind subjects In general, they show relatively little loss in luminosity, and are capable of responding to levels of energy which differ only slightly from those required to stimulate the eye of the normal observer In addition, their visual acuity is almost normal These two facts lead to the conclusion that their deficiency is not the absence of an entire class of cones Rather, it suggests that they may be lacking in one or another of the photopigments found in normal cones

These conclusions have found confirmation in some carefully conducted experiments on spectral response functions (Hsia and Graham, 1957, Wald and Brown, 1965) Spectral response functions representative of protanopes, deuteranopes and normal subjects are presented in Figure 8 111 These functions indicate a systematic loss in sensitivity for the protanope at longer wavelengths It is for this reason that the protanope is often characterized as "red blind" although his actual color perceptions are probably very similar to those of the "green blind" deuteranope The spectral response function for the deuteranope in Figure 8.111 shows a small loss in sensitivity in the short wavelength region of the spectrum, but the loss is not nearly so marked as that for the protanope at the long wavelength end The data in Figure 8 111 were obtained

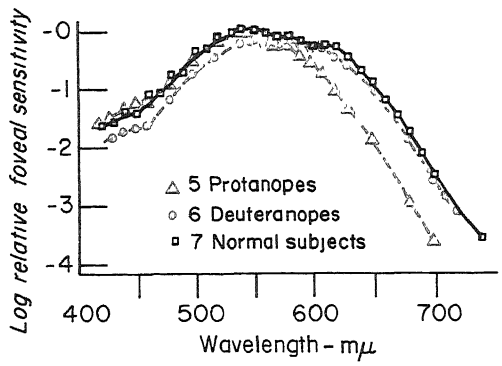

Fig 8 111 Log luminosity for protanopes deuteranopes and normal observers All of the data are expressed relative to the maximum value for the normal observer The protanopes show a luminosity loss in the red and the deuteranopes show a somewhat lesser loss in the green and blue (Hsia and Graham 1957)

without any selective preadaptation They represent the composite spectral response functions which presumably derive from contributions of all available cone pigments as these are combined, probably in the retina

Some indication of the nature of the underlying spectral response function for individual receptors may be obtained by selective bleaching and psychophysical measurements of the spectral sensitivity (Wald and Brown 1965) To isolate the blue receptor, measurements were made against a bright yellow background illumination The green receptor was isolated by making measurements on a background of mixed blue and red, or purple light Measurements of the red receptor were accomplished against a bright blue background The results are presented in Figure 8 112 for a normal observer, a red blind, a green blind and a blue blind observer It is clear that for the normal observer three different spectral response functions are derived against each of the three different conditions of background illumination On the other hand, for the red blind observer, selective adaptation produces only two spectral response functions Against a bright blue background, the function measured for the red blind observer is identical with that measured against a purple background It may be inferred that the red blind observer lacks the long wavelength absorbing pigment Similarly, the green blind observer appears to lack the pigment which absorbs selectively in the middle wavelengths and the blue blind observer seems to lack the pigment which absorbs primarily in the shortest visible wavelengths The color vision of dichromats apparently can be explained in terms of loss of specific cone pigments The selective adaptation studies of Wald provide no evidence for a fusion of two pigment types in a single receptor nor for the convergence of two receptor types on common foci within the system with a resulting loss in their unique individual selectivity

The nearly normal visual acuity of dichromats leads to the conclusion that they are not deplete in total number of retinal cones but that, rather, when a given class of cones is missing it has been replaced by others such that in the protanope there are additional middle wavelength cones and in the deuteranope there are additional long wavelength cones There are insufficient data to charac-

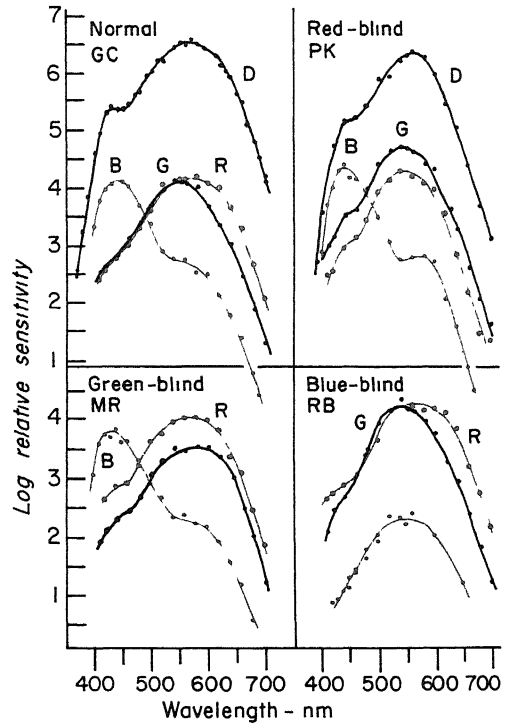

Fig 8 112 Log relative spectral sensitivity functions for normal red blind green blind and blue blind observers Curves labeled D represent the function as measured in the dark-adapted fovea without prior bleaching or selective adaptation Curves labeled *B G* and *R* represent functions obtained against spectrally selected adapting fields which provide for relative isolation of single cone pigments as described in the text It is evident that in the color-blind observers only two spectrally unique functions are obtained (Wald and Brown 1965)

terize the situation in the tritanope It appears that in protanopes and in deuteranopes the mechanisms which stimulate red and green sensations are both stimulated for wavelengths which assume hues of from green through yellow to red in the normal A wavelength of about 490 nm is seen as colorless or neutral by the protanope The neutral point for the deuteranope is at about 500 nm All wavelengths longer than the neutral point evoke a response of yellow in these two classes of dichromats The nature of their color vision deficiency differs in details, but both confuse reds and greens and see colors in shades of blue and yellow Tritanopes see all wavelengths longer than about 575 nm as red and all shorter wavelengths as blue-green, green or sometimes blue

Color Anomaly. There is another class of color deficiency which is termed anomalous trichromacy People with this condition require three primaries to match colors and yet the mixtures which match for them differ in proportions from those made by normal observers There is an anomalous condition for each of the dichromacies, they are therefore categorized as protanomalous, deuteranomalous or tritanomalous In these categories individuals may be found ranging all the way between normal and the dichromat

Hereditary Aspects Color vision deficiency is known to be genetically linked More men are color-blind than women and there are different incidences in different races Among Caucasians approximately 8% of all men are dichromats or anomalous trichromats, only about 0 64% of women are so affected (Hsia and Graham, 1965) Approximately 1% of men and 0 02% of women are protanopes A slightly higher percentage of men, 1% to 2%, are deuteranopes, only 0 01% of women are deuteranopes The occurrence of tritanopes is really too small to be assigned any percentage value Both protanopia and deuteranopia are sex-linked recessive characteristics It is probable that two gene loci are involved on the x-chromosome (Stern, 1960, Francois, 1961, Wald and Brown 1965) It seems reasonable to suppose that the three color vision pigments involve three different opsins which in turn depend upon the operation of three different genes Red blindness and green blindness may represent recessive mutations in which these opsins are not formed

Anomalous trichromia differs genetically from dueteranopia and protanopia The condition breeds true (Waaler, 1927) Wald and Brown (1965) suggest that "the gene that normally specifies the red sensitive pigment is allelic with the recessives for protanopia and protanomaly, and similarly the gene that specifies the opsin of the green sensitive pigment is allelic with the recessives for deuteranopia and deuteranomaly The order of dominance is normal > anomalous trichromia > dichromia"

Tritanopia is apparently not sex-linked A study of 47 tritanopes (Kalmus, 1955) showed 29 to be males and 18 to be females This suggests that the character of the genetic deficiency is autosomal and dominant

Rod-monochromacy is usually said to be a simple autosomal recessive character, i e , not sex-linked In some families, however, evidence for a sex linkage has been found Certain types of cone monochromacy may not be heritable while others probably are (Hsia and Graham, 1965)

Perception of Depth

There is a variety of cues which afford information as to differences in depth, several of which are operative in monocular vision and two of which require binocular vision

Relative Size. The further an object is from the eye, the smaller is its image on the retina Retinal image size thus could afford a cue to depth Nevertheless, retinal image size alone is not a particularly effective cue in the estimation of absolute distance (Gogel, Hartman, and Harker, 1957), even for familiar objects

Linear Perspective. The relative image size of individual objects as a cue to depth may be extended to the image of the entire visual field The texture of objects which recede from the observer in depth grows finer the greater the distance of the particular point under observation Images of parellel lines comprising the edges of three-dimensional rectangular objects tend to converge as they recede from the observer in depth Linear perspective refers to the geometry of projection of a three-dimensional world on a two-dimensional plane and is reasonably considered to be an extension of the relative size factor to the continuum of visual space

Interposition. When two objects are located

at different distances in space, the nearer may intrude between the observer and the more distant object The result will be the partial occlusion of the more distant object and an interruption of its familiar form Ratoosh (1949) expressed the notion formally, stating that a discontinuity in the first derivative of an outline contour affords a cue for discrimination of relative depth of the object forming the contour An illustration of this concept is presented in Figure 8 113 In the part *A* of the figure, one rectangle appears to be located in front of the second in a manner such that it is cutting off the lower left portion of the more distant rectangle The boundaries of the rectangle that appears to be more distant are interrupted by the boundaries of the rectangle that appears closer The contour lines which define what is presumed to be the rear rectangle are thus discontinuous at their point of intersection with the contour lines which define the rectangle which appears to be closer

It is unsatisfactory, however, to attempt to explain interposition entirely in terms of such notions as contour discontinuity A rectangle has four discontinuities, one at each corner, but once the outline is perceived as a rectangle, the discontinuities at the corner have no relevance to depth, they merely confirm rectangularity It is more appropriate to define interposition in terms of the interruption of contours which are expected on the basis of a reasonable assessment of the nature of the figure This is illustrated in part *B* (right) of Figure 8 113 This appears to show a star located in front of a circle Actually, there are discontinuities in the outline contour of the star as well as that of the circle at the point of intersection of the contours of the two figures The discontinuities in the outline of the star conform to expectation on the basis of its shape as a star The discontinuities in the outline of the circle, however, are incompatible with its being a circle unless the star is located in front of it Otherwise, the circle is not a circle but a circular form with a pie-shaped cut-out which just conforms to one of the points of the star For most observers the latter possibility is much less likely than that of a full circle with a star located in front of it (Chapanis and McCleary, 1953) It is thus evident that the cue of interposition is very much dependent upon the observer's knowledge of outline contours of the objects involved

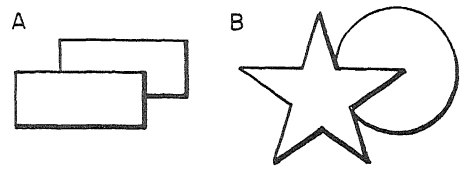

Fig 8 113 Two line drawings which represent the phenomenon of interposition as a cue to the discrimination of relative distance At *A* one rectangle appears to be cutting off a portion of a second rectangle located at a greater distance The contours of the first interrupt the contours of the second rectangle At *B* a star appears to be located in front of a circle In this part of the figure there are discontinuities in the outline boundaries of both star and circle at their intersection The discontinuities in the outline of the star however are characteristic of its shape (Modified from Graham 1965b)

Monocular Movement Parallax. Whenever there is motion of an observer or of objects which are located at different distances with respect to an observer, there is usually an accompanying change in perspective of the objects from the point of view of the observer This is illustrated in Figure 8 114 for a situation where an observer is moving along a line indicated by the arrow Two objects, *a* and *b*, are located in space at the positions indicated The locations of the images of these objects on the retina of the observer are indicated by *a'* and *b'* It is evident that the angle through which the image of *b* sweeps across the retina with motion of the observer from 0_1 to 0_3 is substantially greater than the angle traversed by the image of *a* To the passenger who looks out the side window of a moving car or train, objects near by, such as telephone poles, appear to be moving rapidly in the direction opposite to that of the motion of the vehicle The more distant the object, the less rapid is its apparent motion in the opposite direction Objects at a middle distance fixated by the observer may appear to be stationary, and more distant objects will then appear to be moving in the same direction as the observer Even the slightest motion of the head introduces monocular movement parallax effects which provide important cues to the relative depth of objects in the immediate surroundings Smaller movements are necessary for the discrimination of monocular movement parallax in the horizontal direction than in the vertical (Tschermak-Seysenegg, 1939, Graham et al., 1948)

Accommodation. The accommodative re-

sponse of the eye which alters the physical characteristic of the lens in order to achieve a maximally sharp image on the retina could, logically, serve as a cue to depth If appropriate feedback information is available as to the nature of the motor response necessary to achieve optimum focus of the retinal image, this might provide a cue to the depth of the object viewed When all cues are eliminated other than that of accommodation, however, it is found that this alone does not provide a very accurate basis for the determination of depth (Graham, 1965b)

Convergence. In binocular vision, vergence movements of the eyes result in stimulation of the two foveas by light reflected from the point of regard in the visual world As this point recedes in space, the eyes must diverge As it approaches the observer, the eyes must converge Vergence movements are under the control of the extraocular muscle system and the relative tension in the musculature involved is a possible basis for information as to relative depth of the point of fixation Convergence and accommodation change together in binocular vision With increased convergence, the

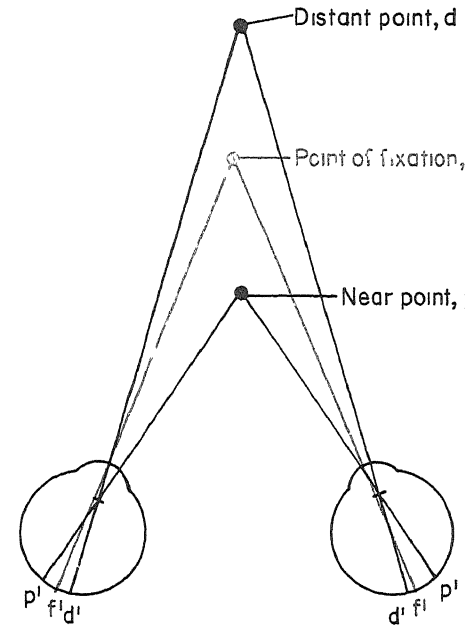

Fig 8 115 Illustration of the doubling of images of objects seen binocularly at depths which differ from the point of fixation For additional information see text

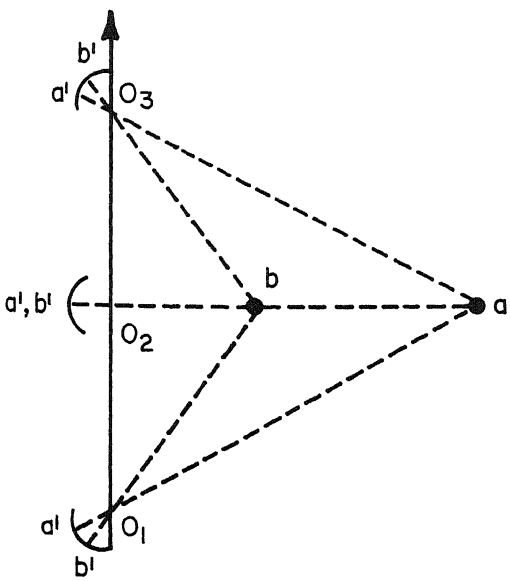

Fig 8 114 Illustration of the relative positions of two objects located at different distances from an observer as he moves along the path represented by the arrow Relative changes in the locations of retinal images of the two objects are shown Such changes in retinal image positions provide the monocular movement parallax cue for distance discrimination

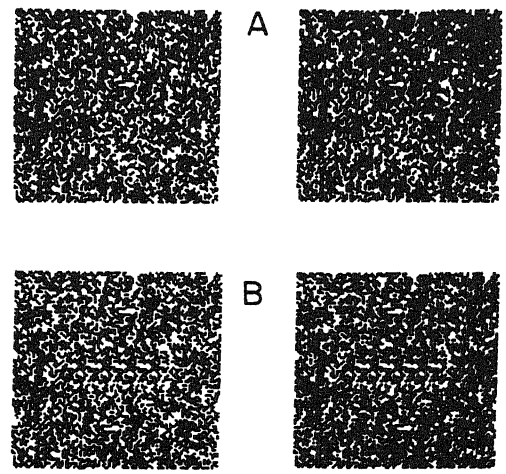

Fig 8 116 Two pairs of random dot matrices which illustrate binocular depth discrimination based on retinal disparity In the upper pair of dot patterns a small square area has been laterally displaced in one of the matrices Otherwise the two patterns are identical The lower two patterns are alike except for three rectangular patterns By first fixating a point closer than the plane of the figure so that there is a doubling of each of the members of a pair of the dot patterns with superimposition of their images on the retina and then carefully adjusting accommodation for clear view of the fused images it is possible to see a square within the pattern which appears to be behind the plane of the page (Julesz, 1964)

eye must accommodate for nearer objects in order to maintain a sharp retinal image A variety of experiments has been performed in which the accommodation and convergence functions are artificially separated The results of these studies do not provide consistent evidence for the comparative evaluation of accommodation and convergence as cues to depth (Graham, 1965b) They do show, however, that convergence like accommodation, is a relatively unimportant cue in the discrimination of depth

Binocular Retinal Disparity The two eyes are displaced in space by approximately 65 mm Thus they provide two different views of the visual world Objects located at different depths are seen in different relative perspectives by the two eyes This can be demonstrated fairly simply as illustrated in Figure 8 115 by fixating the forefinger of the right hand while the forefinger of the left hand is held behind it The more distant finger is seen as double It is clear from the figure that for the left eye, the more distant finger is located to the left of the point of fixation, while for the right eye is is located to the right of the point of fixation The point of fixation is imaged on the foveas of the two eyes The more distant fingertip is imaged on noncorresponding points in the two eyes, to the right of the fovea in the left eye and to the left of the fovea in the right eye (Corresponding points in the two eyes are defined as those points which would be in contact if the two retinas were superposed with the two foveas in contact Thus the temporal retina of the right eye corresponds with the nasal retina of the left eye, etc) If fixation is maintained on the right forefinger and the left forefinger is then brought in closer to the observer, it will again be seen as double, but this time the left eye image will appear to the right of the point of fixation and the right eye image will appear to the left of the point of fixation Again, noncorresponding points of the two retinas are stimulated by the light from the nearer object

In the example given, the effect is a fairly dramatic one in that double images are seen Normally, they are not seen, although with the exception of the object of fixation, parts of the images of most objects in the visual field stimulate noncorresponding points on the two retinas Such retinal image disparity appears to provide a cue as to relative depth When disparity is not great, or when the disparate images are sufficiently removed from the region of the fovea, objects are not seen as double but are seen to be located closer or further away than the point of fixation, depending upon the nature of the disparity Geometrically, there are a number of points in visual space other than the point of fixation which will provide retinal stimulation of corresponding points in the two retinas The locus of these points in space is known as the *geometric horopter* The derivation of the term implies the limiting locus for observation of single images In fact, most points which do not stimulate precisely corresponding retinal locations in the two eyes are not seen as double but are seen as at different depths The geometric horopter was worked out in detail by Johannes Muller (1826) This conception of the horopter is oversimplified, some of the complications which must be considered were worked out by Helmholtz (1924) and by Hering (1861, 1864) A good review of the subject is presented by Ogle (1950)

The recent studies reported by Barlow, Blakemore and Pettigrew (1967) and by Hubel and Wiesel (1970), which demonstrate the existence of cortical cells that respond differentially to certain amounts of disparity particularly in the horizontal dimension, provide a neurophysiological basis for the perception of depth as a result of binocular retinal disparity

Forms can be discriminated in depth solely on the basis of retinal disparity in the absence of any monocular cues as to their identity Julesz (1964) has demonstrated this with the aid of stereo pairs which are comprised of random dot patterns (Fig 8 116) One member of a pair consists of a randomly distributed pattern of dots The other member is identical except that all of the dots within an imaginary outline of some form are transposed laterally with respect to the rest of the dots Dots intruded upon by the transposition are erased The vacated portion of the pattern is refilled with random dots When the two eyes fuse either the dots which have been transposed or the background dots, the resulting retinal disparity of dots not fused is accompanied by the appearance of the form It may appear either in front of or behind the plane of the background depending on the direction of the disparity

5 / TASTE

The sensation of taste is relatively complex Taste is essentially a chemical sense, but the "taste" of food is significantly influenced by responses of pain receptors, and tactual receptors of the mouth, as well as by receptors of smell The way in which a food "tastes" is influenced by its temperature and physical consistency as well as its chemical characteristics One may enhance the taste of food by manipulating it with the tongue while it is in the mouth This serves to distribute the food over different regions of the tongue and mouth in which sensory receptors for taste with differential response characteristics reside In addition, motions of the tongue tend to permit liquids to flow in around the papillae on the tongue, permitting greater access to taste buds in their walls (von Békésy, 1964b) Taste is also influenced by the condition of adaptation of taste receptors Compared with other sense organs, they are highly subject to adaptation, and the taste of any given substance may be significantly influenced by the nature of the materials to which the taste receptors have been exposed in the immediately preceding interval

The presence of certain substances in the blood stream may lead to a sensation of taste peculiar to these specific substances As is true in the case of material taken into the mouth, such tastes tend to adapt out These observations thus indicate that alterations in the chemical constituents of the blood may not only induce tastes but may alter the sensitivity of the individual to the tastes of specific substances The taste receptors themselves are apparently insensitive to mechanical vibration or passive touch, but the texture of foods and the viscosity of liquids certainly influence the nature of the overall experience which we categorize as "taste "

Most persons would agree that taste adds an important dimension to human experience and contributes to our enjoyment of eating or to our rejection of certain foods Although there is some question as to the physiological significance of this for man, tastes may play a highly significant role in maintaining appropriate physiological balance in animals For example, animals with certain food deficiencies have been demonstrated to select preferentially those foods, the taste of which is associated with the substances in which they are deficient (Pfaffmann, 1963, Teitelbaum and Epstein, 1963)

The Sensations of Taste

Concern with the sensory dimensions of taste can be traced back for many years (Boring, 1942) Around the end of the 16th century, nine "basic" tastes were recognized By the middle of the 1700s, this number had grown somewhat by the addition of new tastes and elimination of some of the old A gradual refinement of the list by the elimination of subcategories having components that might be attributed to other than purely chemical stimulation occurred over the years At present, we recognize four fundamental dimensions of taste. salty, sour or acid, sweet, and bitter These four basic sensations were described by Fick in 1864 Acceptance of them has been strengthened by a variety of evidence over the years From these four fundamentals, along with the influences of tactual, pain (Lee, 1954) and olfactory stimulations, the almost numberless varieties of gustatory experiences are derived As we shall see, derived tastes may represent blends of the fundamentals or the effects of interaction which include inhibitory components

Salty tastes are derived primarily from inorganic compounds which ionize in solution The most familiar is sodium chloride, common table salt In addition, the chlorides of potassium, magnesium, ammonium, lithium, zinc, and calcium all taste salty They differ from one another, however, and this is attributed to their stimulation of the receptors for dimensions of taste other than those which mediate

the salty taste In addition to chlorides, the other halides, including bromides, iodides and fluorides, along with sulfates nitrates, carbonates, and tartrates may taste salty The possible contribution of the cation is not clear Compounds of sodium, potassium, lithium, magnesium, and ammonium often taste salty, but sodium acetate does not Heavier halide compounds tend to taste bitter

As is the case for those materials which produce a salty taste, those which produce a sour taste are also electrolytes It is generally agreed that the active agent in this instance is the hydrogen ion The inorganic acids, hydrochloric, sulfuric, and nitric, will taste the same when they are made up in equal concentrations This is not true of organic acids, however Some of these with a lower hydrogen ion concentration than that of hydrochloric acid, for example, may nonethless taste more sour The greater effectiveness of acetic acid than hydrochloric acid for the same hydrogen ion concentration has been attributed to the greater effectiveness of acetic acid in penetrating tissue, and thus, to an actually higher hydrogen ion concentration within the taste buds when acetic acid is employed as a stimulant Another reason suggested by Pfaffmann (1951) is based on the interaction of the saliva with the stimulus Saliva may be a more effective buffer in the case of some stimuli than others Apparently, when acid stimuli are restricted to a region of the tongue from which saliva has been removed, thresholds are directly related to the hydrogen ion concentration

Sweet tastes are primarily associated with organic compounds, specifically the various sugars, along with some polysaccharides, glycerol, and other alcohols, aldehydes, and ketones of the aliphatic series and saccharin, dulcin, and chloroform In addition, some inorganic materials such as lead acetate and diluted alkalis may be sweet to the taste Many of the sweetest tasting organic materials are not electrolytes

As is the case for sweet stimuli, compounds which elicit a bitter taste are primarily organic, particularly the alkaloids (brucine, strychnine, nicotine, quinine, morphine, and others, as well as certain glucosides In addition, bile salts are organic compounds which produce a bitter taste In general, these bitter stimuli are active without dissociation Some inorganic salts including those of magnesium cesium, rubidium, ammonium, and calcium as well as others produce a bitter taste which is attributed to action of the cation in solution Many organic compounds which taste bitter contain NO_2 groups, with two such groups a molecule usually tastes bitter, and with three such groups it invariably does

There appears to be a close chemical relation between many of the stimuli for bitterness and sweetness Derivatives of saccharin, which is intensely sweet, may be quite bitter Phenylthiocarbamide tastes bitter to most individuals and yet it is identical with dulcin, 500 times sweeter than sugar, except for the fact that one oxygen atom of the dulcin molecule has been replaced by a sulfer atom In some cases, isomers of a sweet tasting compound with identical chemical constituents will have a bitter taste

There is a significant relation between the qualitative sensation of taste and the region of the tongue which is stimulated Sensitivity to sweet stimuli is greatest near the tip of the tongue, while sensitivity to bitter stimuli is greatest at the base of the tongue and in the region of the epiglottis Some substances, such as sodium salicylate, rhamnose, and parabrombenzoic-sulfamide give rise to a sweet sensation when applied to the tip of the tongue but elicit a bitter taste when applied to the base of the tongue Magnesium and sodium sulfates cause a salty taste when applied to the tip and a bitter taste when applied to the base of the tongue Apparently the lateral edges of the tongue at about the middle are most sensitive to sour stimuli Salty stimuli appear to be most effective on the tip of the tongue, but elicit a characteristic taste when applied to almost any region of the upper surface and edges, except for the middle region of the top of the tongue, which is apparently insensitive to any chemical taste stimulation These localization phenomena were early interpreted to imply that specific receptors for the four fundamental taste components tend to be, at least to some extent, separated regionally on the tongue The discovery of these geographic distributions of response for sour, salty, bitter, and sweet lends support to the belief that the fundamental components of taste are four in number (Hönig, 1901)

The Peripheral Taste Receptors

ANATOMY AND SENSITIVITY

The primary chemical receptors for taste are the taste buds Most of these are located on the tongue, but some are found on both the hard and soft palate, the mucosa of the epiglottis, and the larynx in the region of the arytenoid cartilages, the mucosa of the pharnyx, and even the mucosa of the lips and cheeks, as well as the bottom of the tongue and the floor of the mouth in some individuals (Bornstein, 1940). In children, taste buds are quite widely distributed and are especially numerous at the tip of the tongue In the adult, the number at the tip is much reduced and the middle portion of the tongue's upper surface is almost devoid of taste buds The taste buds of the tongue are located on the lingual papillae, the many small elevations with which the surface mucosa of the tongue is studded There are three main types of papillae, the filiform, fungiform, and circumvallate The filiform papillae are minute conical structures covering the anterior two-thirds or so of the dorsal surface of the tongue, but they rarely contain taste buds The fungiform papillae are larger, round in shape, and are located mostly at the tip and edges of the tongue Each of these usually holds from 8 to 10 taste buds in the epithelium covering its free surface The circumvallate papillae are the largest of the papillae and are most conspicuous at the posterior portion of the tongue where from 6 to 12 are arranged in a V-formation with the vertex toward the back Their general location is illustrated in Figure 8 117*A* The circumvallate papillae have a central round elevation with perpendicular sides and are surrounded by a sulcus The taste buds are located in mucosa which forms the walls of the circular trench around each papilla There are usually more than 200 taste buds on the perpendicular walls of each papilla and there may be substantially more With advancing age, this number may be drastically reduced (Ary, et al, 1935) A microphotograph of the tip of the tongue which shows various taste papillae is illustrated in Figure 8 118 These have selective responses for the human subject to individual stimulation, both electrically and chemically, as coded in the figure A schematic illustration of a single taste bud in cross section with its microvilli projecting from the lateral wall of a papilla is shown in Figure 8 119 Individual taste buds are oblate, 50 μ in breadth and approximately 70 μ from base to tip They are made up of groups of peripheral supporting cells and elongated receptor cells about 10 μ in diameter The microvilli at the tips of these cells project through the taste pore on the surface of the papilla (Fig 8 120) These are extremely thin, only 0 1 to 0 2 μ in diameter and approximately 2 μ in length (deLorenzo, 1963) The tight packing of the cells suggests that stimulation occurs by reason of contact between the microvilli and solutions which carry taste provoking substances Each taste bud may contain from 5 to 18 sensory cells Innervating nerve fibers penetrate the basement membrane of the receptor organ and arborize upon the surfaces of individual taste

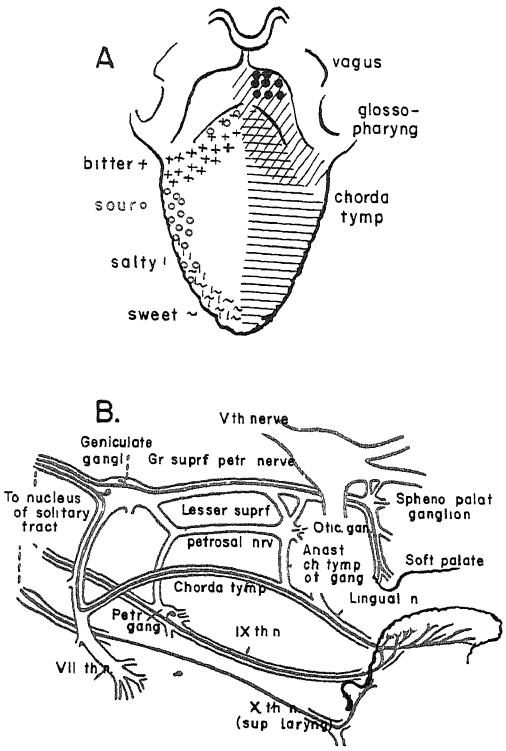

Fig 8 117 *A* Sensitivity of the tongue in different regions for four primary taste qualities Diagonal cross-hatching represents the region innervated by the glossopharyngeal nerve Solid dots show the region innervated by the vagus Horizontal shading represents the region innervated by the chorda tympani (von Békésy 1966)
The pathways of the nerve supplies are shown in greater detail in *B* a sagittal cross-sectional view of the tongue (Modified from Brodal 1959)

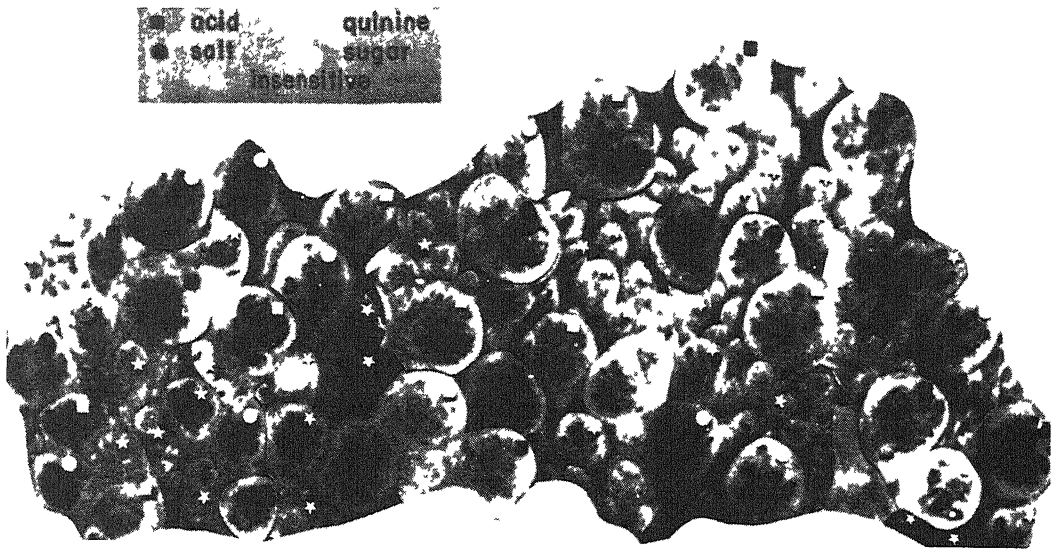

Fig 8 118 Photomicrograph of the surface of the tip of the tongue showing various taste papillae Sensation qualities for electrical and chemical stimulation of each papilla are shown by the various signs Sensation qualities for electrical and chemical stimulation of a given papilla are identical (von Bekésy 1966)

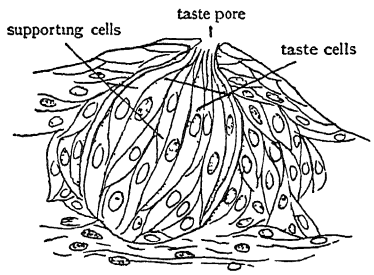

Fig 8 119 Vertical section through a taste bud

cells The suspicion that the sensory cells of taste buds "wear out" and are replaced after a fairly brief life cycle has been confirmed in several experiments (Beidler, et al , 1960, de-Lorenzo, 1963) These studies reveal that the sensory cells arise from division of the surrounding supporting cells and then migrate toward the center of the taste bud prior to degeneration The entire process probably occupies no more than 3 to 5 days for the rat, perhaps 10 to 15 days for the rabbit. Beidler (1963) has suggested that the response characteristics of these cells for a specific stimulus may change during their life cycle, but this raises serious theoretical problems if true (Davis, 1963), and there is some evidence which tends to refute the notion (von Békésy, 1964b, 1966).

The evidence for four fundamental taste sensations has been interpreted to suggest that there may be four distinct types of taste buds, each specialized to respond to certain types of stimuli more effectively than others Although there is some evidence that this may be the case (von Bekésy, 1966), there is other evidence, apparently equally good, which contradicts the idea Kimura and Beidler (1961) recorded from individual taste receptors of the rat and hamster Their results showed that a microelectrode inserted through the taste pore of a single taste bud responds with a graded potential to stimulation provided through a small pipette in the region of the taste pore From a resting level of from −50 to −95 mv relative to a remotely located indifferent electrode, there was an increased positivity by as much as 10 mv upon chemical stimulation Substantial responses could be obtained from a single taste bud to stimuli for salt, bitter, sweet, and sour responses The response might be greater for one chemical modality than another, but variation in concentration could easily equalize the responses Highly specific taste receptors that respond to only one type of stimulation were not found Many of the taste cells did not respond to sucrose but a substantial number did The responses in millivolts of the hamster taste receptor to basic stimuli of four taste qualities are presented for each of eight taste receptors in Table 8 4

Table 8 4
Response in millivolts of the hamster taste receptor to basic stimuli of four taste qualities

Taste Receptor	0 1 M NaCl	0 1 M Sucrose	0 02 M Quinine	0 01 M HCl
1	10 5	2	4 5	—
2	8 5	2	7 5	0
3	9	1	4 5	—
4	11 5	5	8	22 5
5	10	6 5	9	12 5
6	6 5	1 5	5	—
7	9 5	2 5	7	9
8	14	0	5	14

From Kimura and Beidler, 1961

Note that all of these receptors responded to salty and bitter stimulation and that all responded to at least three of the solutions for the four different taste qualities If individual taste buds were strikingly more sensitive in their response to one of the four modalities than the other three, it might be presumed that, even though they respond to a variety of solutions, the individual cells mediate a highly specific qualitative sensory response The data of Table 8 4 however, do not appear to support such a notion These data, of course, are electrical measurements in the peripheral receptors of an infrahuman species It may, therefore, be dangerous to generalize too quickly from these data to theories of taste reception in the human

Several interesting experiments have been performed on the subjective responses of humans to stimulation of individual papillae, both electrically and chemically (von Békésy, 1964b, 1966) von Bekésy (1964b) was able to stimulate individual papillae of human subjects with s small gold-tipped electrode With a tip diameter of $\frac{3}{10}$ mm , only a unitary taste response was obtained Responses of sour, salty, bitter, and one case of sweet were elicited by electrical stimulation of specific papillae Each papilla mediated only one taste quality There was no change in the quality with movement of the stimulating tip over the surface of a single papilla The electrically elicited taste qualities were not identical with those elicited by chemical stimulation This was attributed to the probability that chemical stimuli are effective in the excitation of several papillae and result in a combined excitation with a resulting qualitative change Some papillae were found which appeared to be two simple papillae fused together These mediated dual response qualities Larger papillae were found infrequently which mediated as many as three taste qualities von Békesy (1966) followed up his study of subjective response to electrical stimulation with one of subjective response to chemical stimulation An individual papilla was pulled up with a suction tip and a drop of solution placed on its lateral wall When the tongue was maintained relatively dry in air of 30% humidity, the walls of the papillae apparently would support a drop of test solution without allowing it to flow onto the taste buds of neighboring papillae The results of the chemical stimulation study supported those obtained with electrical stimulation Individual papillae mediated only one qualitative taste response unless they were the larger, apparently compounded, papillae More importantly, individual papillae gave no response whatsoever to solutions which were inappropriate for the stimulation of their particular quality of sensation The quality was not changed by a change in the concentration of solution, and the quality remained the same when a single papilla was stimulated either chemically or electrically These results are very difficult to reconcile with those reported by Beidler and his colleagues as referred to above

There is some additional, albeit indirect, evidence for four differentially responding receptor cells each of which may uniquely mediate a given taste quality von Skramlik (1963) investigated the effects of application of a variety of anesthetics on the tongue He found differences in the change of sensitivity for the different sensory qualities of taste, and differences in recovery time, including in some instances a period of hypersensitivity The bitter "substrate" was most sensitive to anesthesia The effects on the "substrates" which mediated the other three qualities varied with the different anesthesias The results provide a clear indication that the four "substrates" (receptors?) are quite independent Nevertheless, the question of whether there are just four unique receptors for taste in the human gustatory system or whether there are many variations in the taste receptors (Erickson, 1967) must remain an open question at this time

NEURAL INNERVATION OF THE PERIPHERAL RECEPTORS

The nerve fibers which penetrate the basement membrane of taste buds are dendritic branches of neurons, each of which innervates a number of cells They arise in the seventh and ninth cranial nerves The chorda tympani branch of the facial nerve (VII) sends fibers to taste buds which are distributed over the anterior two-thirds of the tongue This distribution is illustrated in Figure 8 117*A* by the horizontal lines on the right hand side of the figure The glossopharyngeal nerve (IX) sends fibers to taste buds which are in the posterior one-third of the tongue This region is illustrated in Figure 8 117*A* by the oblique lines Taste buds which are located on the pharyngeal aspect of the tongue, as well as those on the soft palate, the epiglottis, and in the region of the arytenoid cartilages receive innervation from the vagus nerve (X) This is illustrated in Figure 8 117*A* by the solid dots on the base of the tongue A lateral view of this innervation is shown in Figure 8 117*B* There are individual differences in the nature of the pathway followed by the fibers of the chorda tympani This branch of the facial nerve is so named because it passes over the ossicles of the middle ear not far from the tympanic membrane This location is accessible in animals and has also been accessible in human patients undergoing surgery on the middle ear

The trigeminal nerve (V) mediates sensations of touch, temperature, and pressure from the entire buccal mucosa in addition to the common chemical sense It does not contain fibers which are associated with taste buds, but, as indicated above, aspects of what we commonly call taste are undoubtedly influenced by activity of the trigeminal nerve

A variety of experiments has been performed in which the electrical activity of single fibers of the primary afferent neurons associated with taste buds has been measured In an early study, Pfaffman (1941) showed that various single fibers in the chorda tympani of the cat showed different patterns of excitation by solutions applied to the tongue Certain fibers were most responsive to acid stimuli, others to both acid and salt, others to acid and quinine Sugar proved ineffective in stimulating any of the fibers from which recordings were made The spike discharge patterns of individual fibers did not show any unique characteristics associated with the nature of the stimulus This was interpreted to support the specific nerve energies theory of function of the sensory nervous system That is, the qualitative nature of the information is determined by the specific fibers involved and not by their pattern of discharge Additional work has been done on cats by others (Cohen et al , 1955) as well as on rats, hamsters, and rabbits (Fishman, 1957, Pfaffman, 1955) The dog is of interest because, unlike the cat, it is behaviorally responsive to sweet substances

In a recent experiment, it has been shown that different sugars differ markedly in their effectiveness as stimuli when the criterion of response is the activity in single fibers of the chorda tympani, or the integrated response of the chorda tympani nerve bundle (Andersen et al , 1963) Using 0 5 M solutions of both monosaccharides and disaccharides, it was found that the most potent stimulus was D-fructose followed by sucrose, D-glucose, maltose, D-galactose, and lactose The order for the monosaccharides was D-fructose, D-glucose, and galactose The rank order of potency of the disaccharides appeared to be determined by the potency of that portion of the molecule which combined with the glucose present in all of the disaccharides Some fibers were found which were responsive to only the most potent stimulus, D-fructose The integrated activity of the chorda tympani provided results which were in agreement with those obtained on single fibers as to the relative potency of the stimuli employed These results, in turn, were in good agreement with the results of behavioral studies on human subjects

Some fibers were found which responded both to salt and to sugar Even when fibers were not responsive to salt, prior stimulation with a salt solution tended to inhibit the response to sugar It is tentatively suggested that the inhibitory effect of salt on the response of some cells which respond to sweet stimuli may be a result of the electrostatic binding of salt on the sites which must be occupied by sweet solutes for the stimulation of receptors Among fibers responsive to both sugar and salt, some were more responsive to sugar, others more responsive to salt, and still others equally responsive A third type of fiber was responsive to salt alone A summary of these findings is illustrated in Figure 8 121

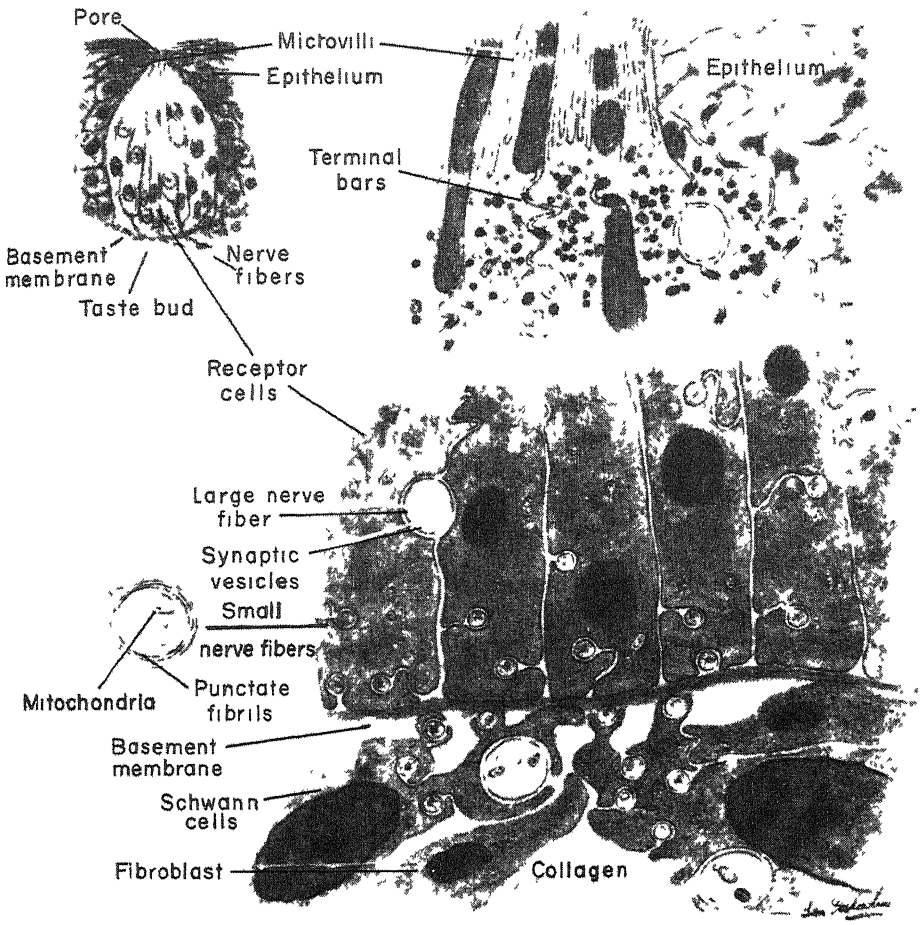

Fig 8 120 Ultrastructure and organization of the taste buds in the papilla foliata of the rabbit (de Lorenzo 1963)

Although some of the single fiber studies indicate exclusive response characteristics associated with a given fundamental taste dimension, it is more typical to find fibers responsive to two or more of the chemical mediators of different fundamental tastes The question arises as to whether any interpretation can be based on these results as to the probable nature of the primary receptors, or their connections to the nerve fibers which carry information from them to the central nervous system It is fairly obvious that many fibers are associated with peripheral terminations on more than one type of receptor, if indeed there are but four receptor types Conflicts between the microelectrode studies of single taste buds and the behavioral studies of von Békésy do not permit any firm conclusion at this time, but some of the single fiber work is suggestive of the possibility that there are but four peripheral receptor types (Ogawa et al , 1968, Frank and Pfaffmann, 1969)

Frank and Pfaffmann have studied the responses of single fibers of the glossopharyngeal nerve and the chorda tympani of the rat in terms of their sensitivity to taste stimuli for each of four different qualities, salt, acid, bitter, and sweet Fibers were classified as responding to a stimulus when they showed at least a 50% increase in response rate during the first 5 sec of stimulation One-quarter of the fibers showed response rate increases of 500% or more to more than one of the stimuli employed An analysis of their data on the glossopharyngeal fibers and unpublished data on chorda tympani fibers has been made Responses occurred in the way they would occur to individual stimuli and each of the six pos-

sible pairs of the four stimuli employed if the sensitivities to the four stimuli are independent and randomly distributed among the innervating fibers Agreement with the hypothesis that sensitivities to the four stimuli are mutually independent events, each with a specifiable probability, tends to confirm the supposition that there are, indeed, just four taste primaries It does not, of course, prove the existence of four independent peripheral receptors

The primary taste fibers in the facial nerve, the glossopharyngeal nerve and the vagus, enter the brainstem and then form a descending tract which terminates in the nucleus of the solitary tract of the medulla Facial and glossopharyngeal fibers terminate in the rostral portion and vagal fibers in the caudal portion (Pfaffman et al , 1961) Secondary neurons which arise in the medulla ascend the brainstem through the mesencephalon in close proximity to other fibers from the face, mouth, and tongue which mediate the cutaneous sense and terminate in the arcuate nucleus of the thalamus The tertiary neurons of the afferent pathway from the thalamus terminate in the cortex near the lower end of the postcentral gyrus in the region of the fissure of Sylvius of the parietal cortex

Physiological studies of these pathways at various locations have been conducted Makous et al (1963) recorded from units of the anterior solitary tract of the medulla and its associated nucleus Responses were found to most of the taste stimuli employed In addition, the same region and immediately overlapping regions produced responses to tactile and temperature stimulation Differences in the response to taste stimuli were observed with respect to the frequency of discharge but no obvious classification of these responses was possible

Higher in the system, single units in the arcuate nucleus of the thalamus may be driven by taste stimulating solutions (Blomquist et al , 1962) Lesions of this region in the monkey thalamus have been shown to produce gross deficits in ability to discriminate differences in taste quality (Patton et al , 1944)

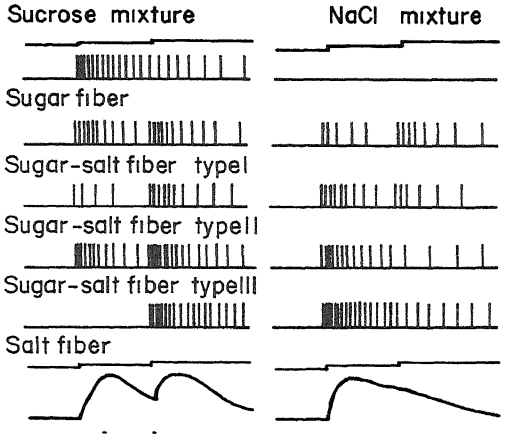

Fig 8 121 Response patterns of various types of fibers which respond to sugar or salt or a combination of the two in solution (Andersen et al 1963)

Experimental Study of Taste Sensation

PSYCHOPHYSICAL STUDIES OF TASTE

Measurements of the absolute threshold concentrations of various taste stimuli are exceedingly difficult to make This is attested by the variability of the results of such studies as these are reported in the literature The methods employed are critical and may greatly influence the results obtained Sapid, or taste provoking, substances may be allowed to flow over an isolated region of the tongue through a glass tube which has a small opening pressed against the tongue The size of the opening and the region of its application will both be relevant variables The temperature of the solution is another variable of considerable importance (Sato, 1963, 1967) Another approach has been to permit the sipping of solutions of material which then can be moved about in the mouth and permitted to stimulate large areas of the surface of the tongue (Anderson, 1950) More precise results may be obtained by the use of a single drop of material (Holway and Hurvich, 1937), or, at the extreme, an effort may be made to stimulate a single papilla Kiesow (1898) attempted to accomplish this with the use of a pointed brush which held the stimulus solution Much more recently, the procedure has been employed by von Békésy (1966) in a study where individual papillae were lifted up from the substrate with a suction tip, and a minute quantity of a chemical stimulus was applied to selected sites on the surface of a given papilla

Absolute thresholds as these were reported

Table 8 5
Absolute Thresholds

Substance	Per Cent Concentration (approx)	Molar Concentration
Sucrose	7×10^{-1}	2×10^{-2}
Sodium chloride	2×10^{-1}	$3\,5 \times 10^{-2}$
Hydrochloric acid	7×10^{-3}	2×10^{-3}
Crystallose (sodium salt of saccharin)	5×10^{-4}	2×10^{-5}
Quinine sulphate	3×10^{-5}	4×10^{-7}

Stevens, 1951

by Pfaffman (1951) are presented in Table 8 5 Values are given for both percentage concentration and molar concentration Since the latter affords an indication of the relative number of molecules of the solute involved, it is perhaps a more meaningful specification Reasonable agreement has been obtained with these threshold values for sucrose and for sodium chloride but widely different results are reported by others for hydrochloric acid, saccharin, and quinine sulfate It is reasonable to assume that the methods of testing, temperature and individual differences all have played a role in these discrepancies which are found in the literature Even the values obtained for one subject differ appreciably from time to time, a phenomenon which may reflect changing concentrations of materials in the blood stream as mentioned above

For some substances the interindividual variability in sensitivity is extremely great A dramatic example is that of phenylthiocarbamide Relative sensitivity to this material is believed to be genetically linked The normal threshold is of the order of from 0 001 to 0 0001% solution For many years it was believed that some individuals were simply incapable of tasting this substance Setterfield et al , (1936) have demonstrated that, when the concentration is sufficiently high, a threshold value is reached for the so-called "nontasters "

The discrimination threshold, or amount of increase in concentration necessary for discrimination of a substance against a background level to which the tongue has been adapted, has been studied As the concentration of the background level is increased the relative amount of increase decreases, as is so for most sensory modalities The ratio between the increment and the background is of the order of one-half to approximately one-tenth The value depends, in addition to the concentration of the background, on the particular taste quality under investigation (Kopera, 1931, Holway and Hurvich, 1937)

Discrimination studies are complicated by the very rapid rate of adaptation of the taste mechanism The weaker the concentration of a substance, the more rapidly its taste will adapt out Even with quite high concentrations, however, adaptation will be virtually complete within 2 to 5 min (Krakauer and Dallenbach, 1937, Abrahams et al , 1937)

For most subjects and for most taste substances, there appears to be an optimum temperature for maximum sensitivity in the neighborhood of 35° C for the human (Fig 8 122) (Sato, 1963) An increase in temperature may result in lower thresholds and increased time required for adaptation (Hahn, 1936) This effect was noted for temperature increases below the optimum level of about 35° C however

It is of interest to consider the way in which stimuli for the so-called fundamental tastes combine to produce complex tastes The richness of our taste experience suggests that most familiar tastes are in fact the result of excitation of more than one type of sensory receptor Nor are the interactions among receptors simply additive Depending upon relative concentrations, the application of a sugar solution to one region of the tongue may enhance the sensitivity to salt stimulation in another region of the tongue or inhibit it A low concentration

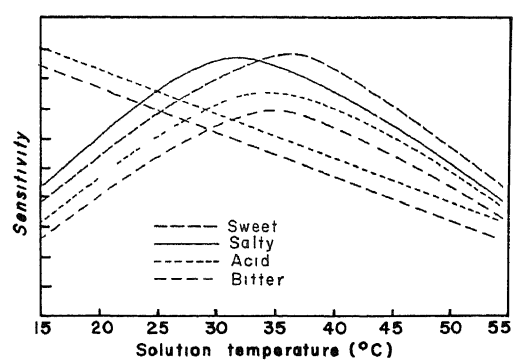

Fig 8 122 Relationship between taste sensitivity of human subjects and temperature of taste solutions Curves represent results for 27 Japanese girls Most showed maximum sensitivity to salt and sugar between 30° and 40° C Half showed a maximum for their sensitivity to acid and bitter and the remaining half showed a regularly declining sensitivity to acid and bitter with increasing temperature (Sato, 1963)

of sugar results in enhancement while a high concentration results in inhibition (Bujas, 1934) Whenever relatively large regions of the tongue are stimulated, interaction effects may be expected no matter what the stimulus Nonetheless, it is possible that some stimuli do afford a taste sensation which is of a fundamental character, that is, basic to the specific receptors for one of the four fundamental taste modalities von Békesy (1966) has suggested that hydrochloric acid may be such a stimulus for "sour," and that quinine may be such a stimulus for "bitter " The subtle differences in taste for different forms of sugars suggest that none of these may elicit the fundamental taste In any case, it might be difficult to distinguish which sweet taste is most nearly representative of the fundamental One device which has been employed by von Bekésy to answer the question is to adapt the tongue strongly with solutions of salty, sour, and bitter substances before applying sweet solutions This procedure results in a more uniform sensory effect of the sweet stimulation which is somewhat different from that elicited by any of the sweet tasting substances without preadaptation, and may provide a method of experiencing the fundamental quality of "sweetness "

Differences in the studies of the response of individual papillae to chemical stimulation by Kiesow (1898) and von Bekesy (1966) may be explainable in terms of a difference in methodology von Békésy was very careful to keep the tongue's surface relatively dry He lifted the papillae to be stimulated out of the surface of the tongue with a suction tip before applying the chemical solution to their sides He observed that the solution remained in place after application without flowing out and providing possible contact with other papillae He explains this on the basis of the argument that the tissue is relatively viscous at its surface and impedes the flow of liquid Were the surface moist, a drop of solution would flow out rapidly and come in contact with other receptors This may have occurred in Kiesow's work Where von Békésy found individual papillae to be, in general, responsive to only one set of stimuli and productive of only one taste quality experience, Kiesow found such exclusively responsive papillae to be in the minority None was found which responded exclusively to bitter stimuli The work of von Békésy is the only work which does report exclusive sensitivities

ELECTRICAL STIMULATION OF THE TASTE RECEPTORS

Electrical stimulation has long been known to be effective in the production of taste sensation With DC stimulation and the anode placed on the tongue, the taste is alkaline This result is attributed to electrolysis and the change in concentration of cations and anions in the region of the electrode when its polarity is reversed An alternating current has been employed in an effort to reduce the electrolytic effect and determine whether direct electrical stimulation may elicit taste With relatively large electrodes, there is a clearly discernible change in the quality of the taste sensation provoked with a change in the frequency of stimulation At very low frequencies, a salty taste may be elicited, at intermediate frequencies, the taste will be sour, and at high frequencies, the taste changes to bitter (von Békesy, 1964b) On the other hand, when the diameter of the stimulating electrode is greatly reduced, a unitary taste experience is provoked, quite independent of frequency These relations are illustrated in Figure 8 123

von Békésy (1964b) used short, pulsatile stimuli of 0 5-msec duration in order to minimize electrolytic effect With a small, gold-tipped electrode, it was possible to stimulate individual papillae These proved chemically responsive to only one taste substance, salt, acid, bitter, or sweet, or to nothing No re-

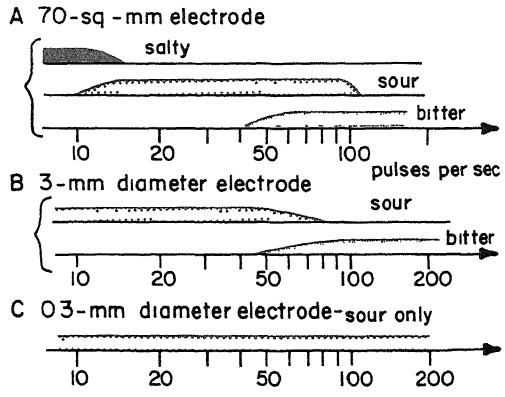

Fig 8 123 Relation of taste quality to frequency of electrical stimulation for each of three stimulating electrodes The quality of taste is seen to change from salty through sour to bitter with a 70mm ^{2} electrode (*A*) the transition is from sour to bitter for a 3-mm diameter electrode (*B*) and taste quality is consistently sour for a 0 3-mm diameter electrode (*C*) With the small elec trode changes in quality could be achieved by selective stimulation of different papillae (von Békésy 1964b)

sponse to more than one stimulus was found except in the case of the double papillae which have been described above These all proved to be combinations of salt and acid sensitivity The response of a given papilla was always consistent and was never found to change with a change in the location of stimulation on its surface Under the conditions of stimulation employed, a taste sensation was evoked only with a positive electrode This suggests that taste induced under a cathode must be attributed to ionization effects With small electrodes and repeated short pulse stimulation, changes in the nature of the taste with increased current did not parallel those changes found with increased chemical concentration On the other hand, with large electrodes employed under conditions where electrolytic effects may be prominent, changes in taste were found to be the same for comparable changes in current or the concentration of a stimulating solution

Using two stimulating electrodes on different papillae, von Békésy was able to show summative effects when papillae of the same character were stimulated, and inhibitory effects for stimulation of papillae representing different taste dimensions, for example, bitter and sweet These results suggest lateral interaction effects which may be either excitatory or inhibitory depending on the nature of the receptors involved The qualitative nature of the tastes elicited by electrical stimulation were comparable for salty, sour, and bitter with tastes produced by appropriate chemical stimuli for these qualities On the other hand, the subjective taste quality for stimulation of a "sweet" papilla differed from the taste elicited by the various sugars It was roughly comparable, however, to the taste elicited by sugar after preadaptation of the tongue with bitter, sour, and salty solutions as described above

Theories of Taste Sensitivity

It is not yet possible to argue with complete conviction for four distinct receptor types which correspond to the four fundamental taste qualities generally recognized Nonetheless, for the human taste process, this seems the most attractive of the various possibilities It is evident that there are interactions among the individual taste receptors within the tongue, and probably also within the other mucosal surfaces in which taste buds are found Taste buds having qualitatively different response characteristics must converge on single primary neurons It is, thus, the pattern of response in the population of neurons which mediate taste which determines the quality of taste (Adrian, 1963) The assignment of a critical role to pattern of response in a population of fibers is almost certainly correct, at least for any but simple tastes, whether one accepts the notion of four fundamental receptors or subscribes to the idea that there may be a variety of combinations of receptors (Erikson, 1965) It is only the two experiments of von Békésy (1964b, 1966) which provide direct support for four unique receptors corresponding to the four fundamental taste qualities, but these experiments appear to have been carefully executed and are relatively convincing They stand in opposition to work which was performed on infrahuman organisms (Kimura and Beidler, 1961) As von Békésy has pointed out (1966), it is reasonable to expect taste to be mediated by a selective chemical action on different organs of taste Certain drugs which impair taste do so selectively Gymnemic acid (Shore, 1892) extinguishes sensitivity to sweet and bitter substances with little if any effect on sensitivity to salty and sour stimuli Cocaine abolishes all taste but the different qualities disappear sequentially in the order of bitter, sweet, salty, and sour These facts may be argued to support the notion of four fundamental taste receptors, although they are clearly not conclusive arguments As indicated above, however, the pattern of responses in individual fibers is also compatible with the notion of four independent peripheral receptors

Like taste, the sense of smell is a chemical sense Perhaps it is even a purer chemical sense than is taste As we have seen, the 'taste" of a food is influenced by tactual stimulation dependent upon the texture and other physical characteristics of food, as well as its odor and its capability for stimulating pain endings which give rise to activity in the trigeminal fibers The contributions of other sensory systems to "smell" are somewhat less This is true for two reasons In the first place, the chemical sense of smell is very much more sensitive than that of taste Secondly, the sense of smell is aroused by chemical material suspended in the air we breathe, and hence, textural qualities are nonexistent It is true that some odors are accompanied by stimulation of the common chemical sensory system mediated by the trigeminal nerve, in which case we may characterize odors as "pungent" or sharp In at least one case, it is probably true that what we believe we are smelling we are in fact tasting This is so for chloroform, which stimulates the taste buds at lower levels of concentration than those required for stimulation of the olfactory receptors Although the conscious concomitants of smell are relatively unspecific compared with the senses of vision and hearing, the sense is an extremely important one for the adaptation of the organism to its environment For many organisms it plays an important role in preservation of both the individual and the species Olfactory stimuli may be paramount as sexual signals for insects and lower animals Although very much more subtle, and probably not requisite for survival, they also play a role in this capacity for the human Information as to the presence of enemies is provided by the olfactory mechanism along with information for the predator which aids him in finding food Food-seeking in many species is partially dependent upon the characteristic odors of appropriate foodstuffs

Olfactory Stimuli

Although it is very difficult to obtain quantitative data on the subject, olfactory stimuli are recognized, for human subjects, to have very strong associative links with past experiences The way in which a characteristic odor may evoke recollection of places and events of the past with remarkable clarity is a fairly common experience

A common problem with the chemical senses is the difficulty of characterizing the stimulus with respect to those aspects of its nature which determine both the quality and the intensity of the sensory experience In general, intensity is related to concentration, but there may be qualitative changes associated with changed concentration as well as intensitive changes In addition, different stimuli, having more or less intense sensory effects cannot easily be categorized in terms of their physical action on the receptors of the system Some substances are particularly effective in stimulating the olfactory sense These include mercaptan and artificial musk which can be detected when present in the amount of one part to several billion parts of the air inspired Other particularly effective stimuli include butyric acid, iodoform, and oil of peppermint It has been estimated that little more than 4×10^{-11} mg of methyl mercaptan/cm ^{3} of air can be detected, and approximately 4×10^{-8} mg /cm ^{3} of artificial musk is sufficient for discrimination of the presence of this material The difference in sensitivity of the sense of taste as compared with that of smell is exemplified by the fact that the concentration of ethanol in solution on the tongue must be nearly 25,000 times as great as the concentration of this material required to stimulate the olfactory sense A relatively small increase in the concentration of alcohol, perhaps by a factor of 3 over that which just stimulates taste, results in a burning sensation by reason

of the stimulation of the receptors for common chemical sensitivity and the resulting trigeminal excitation The concentration of ethanol which can be smelled must be increased nearly 60,000 times before an acrid sensation is elicited in the nostrils

PHYSICAL PROPERTIES OF OLFACTORY STIMULI

In order to be carried to the olfactory receptors, a potential stimulus must be present in air Thus, there is a relation between the volatility of a material or its vapor pressure and its effectiveness as an olfactory stimulus This relation is by no means perfect, however Certain materials, such as musk, have a relatively low volatility, and yet are characterized by a very prominent odor Apparently, this results from a very high effectiveness of the molecule of the substance as a stimulus

Stimulation of the receptor cells in the olfactory mucosa cannot be accomplished unless the stimulants can penetrate the aqueous barrier presented by mucus Effective stimuli are, thus, also water soluble In order to penetrate receptor cells themselves, they must also be lipoid or fat soluble Effective stimuli do have high lipoid solubility and it is, therefore, concluded that solubility in the receptor cell substance is a requisite characteristic There are homologous chemical series, such as alcohols, where solubility changes as a function of position in the series The lower alcohols are highly water soluble, where higher alcohols have a lesser water solubility but high lipoid solubility It turns out that those alcohols in the middle of the series with fairly high solubility in both water and lipoid have the strongest odor Examples of compounds having good solubility in both media include chlorobenzol, brombenzol, ether, and citral Comparisons of various materials suggest that lipid solubility may be slightly more important than water solubility in determining the effectiveness of a stimulus

There are other physical characteristics of materials which appear to be related to their effectiveness as stimuli for the olfactory mechanism So far, however, none of these has permitted any clear-cut theoretical interpretation of the nature of the olfactory process For example, it was first noted by Faraday that strongly odorous materials are also characterized by relatively strong absorption in the infrared region of the electromagnetic spectrum The refractive indices of many odorous materials tend to be very close to a value of 1 5 In addition, the Raman shift of odorous substances tends to be confined to a range of 140 to 350 nm

CHEMICAL COMPOSITION OF ODOROUS MATERIALS

There are certain chemical relations among substances which are associated with their effectiveness as odorous stimuli For example, ethyl, propyl, and butyl acetates all have a characteristic acetic odor Amyl acetate, on the other hand, does not Aspects of the characteristic pineapple odor of amyl acetate can be detected in butyl acetate, however, and the acetic odor is relatively weak in butyl acetate In propyl acetate, the pineapple odor is detectable but the acetic odor is very much stronger In ethyl acetate, the acetic odor predominates Thus, although ethyl acetate and amyl acetate smell quite dissimilar, there is a discernible transition from the odor of one to the other through the series of acetates

There are many quite dissimilar chemical compounds which may have very similar odors On the other hand, identical chemical compounds which differ only in the physical conformation of the molecule may have very different odors This has given rise to the speculation that the shape of the molecule may be a determining factor in its ability to elicit a sensation of odor Such an idea was first put forward by Lucretius (Amoore et al , 1964) It has been explored quantitatively in more recent times and is discussed further below

Of the approximately 30 elements which are found in a free state in nature, all are without odor When heated, arsenic evokes the odor characteristic of garlic but it is odorless as found naturally Relative position of an element in the periodic table appears to have some relation to its odor-producing capability in compounds Sulfur, selenium, and tellurium are all in the sixth group of the table and when combined with hydrogen, methyl, or ethyl groups have disagreeable odors The halogens are all in the seventh group of the periodic table These are associated with a variety of odorless compounds The compounds which stimulate the sense of smell tend to be organic,

but this is not an invariable rule To date, no clearly specifiable dimension of a chemical stimulus has been identified which will permit the specification of either its quantitative or qualitative effectiveness as an odorous stimulus

The Dimensions of Odor

Our language is rich in words for the characterization of odor Odors may be pleasant or unpleasant as well as relatively neutral, and in each of these classifications there are wide qualitative variations It has been estimated that man can distinguish literally thousands of different odors (Wright, 1964) An odor which is not unpleasant may, in increased concentration, become unpleasant although some aspect of its nature is recognized as qualitatively the same

There have been many attempts at the classification of odors Such efforts are usually motivated by the hope that they will provide clues as to the nature of the odor discrimination process, perhaps identifying primary responses from which all of the variations in this sensory dimension are compounded One of the first to develop a set of "primary" odor characteristics was Linnaeus in the 18th century His listing was elaborated by Zwaardemaker (1925) who proposed nine different categories The basis of his proposal was purely subjective, but this alone is no reason to dismiss it Subjective evaluations of sensory experience may provide important clues to the physiological bases of sensory processes A later classification proposed by Henning included six primary odor qualities, five of which corresponded to five of those proposed by Zwaardemaker (Henning, 1916) Another modification, the Crocker-Henderson system, reduced the number to four, three of which corresponded to three of Zwaardemaker's primaries and one of which (acid) was new (Geldard, 1953) It would seem more appropriate to include acid as a taste quality than a smell quality More recently, Amoore (1952), on the basis of a count of the frequency with which various chemical compounds are characterized as having a certain odor, arrived at a list of seven primary odor qualities. Of these, five are found in the earlier list of Zwaardemaker These qualities are presented in Table 8 6 It is interesting to note that only in the case of fragrant or flowery is there agreement among all four of the odor classifications None of the classifications provides sufficient numbers of primaries to permit the range of qualitative discriminations of which the olfactory sense is capable, according to Wright (1964) The basis for discrimination of odors remains unknown It is the hope of investigators in this field that patterns may emerge which will reveal relationships among some aspect of the physical stimuli, the neural activity engendered within the olfactory system, and the qualitative description of the odor experience No satisfactory categorization of primary odors exists at the present time

Table 8 6
Comparison of several classifications of the primary qualities of odor

Zwaardemaker	Henning	Crocker-Henderson	Amoore
Ethereal	Fruity		Ethereal
Aromatic	Spicy		Camphor
Fragrant	Flowery	Fragrant	Floral
Ambrosiac			Musky
Alliaceous			
Empyreumatic	Burnt	Burnt	
Hircine		Goaty	
Foul	Foul		Pungent
Nauseous			
	Resinous		Putrid
		Acid	
			Peppermnty

The Olfactory System

PERIPHERAL RECEPTORS

Olfactory receptors are located within the olfactory epithelium high in the nasal cavity The olfactory epithelium is continuous with the nonsensory nasal mucosa, but brownish-yellow in color due to pigmentation of the supporting cells which it contains This sensory surface is approximately 250 mm ^{2} in area within each nostril and lines the olfactory cleft Its location is illustrated in Figure 8 124

The position of the olfactory mucosa is such that it may not be exposed to the molecules carried by inspired air on each inspiration It has been suggested that the molecules of odorous materials, which are usually volatile, may reach the olfactory mucosa by diffusion It seems unlikely that this is a major basis for the mediation of the olfactory response, however Diffusion is certainly of importance,

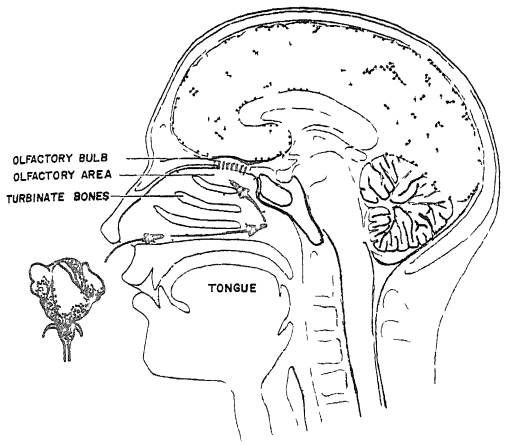

Fig 8 124 Parasagittal cross-section of the head showing the three turbinate bones the olfactory area and the termination of the endings of nerves from the olfactory bulb in the olfactory epithelium The passage of air bearing odorous substances is shown by arrows (Amoore et al 1964)

but maximum exposure of the olfactory epithelium to odorous materials requires an inspiration of more than average forcefulness, or a "sniff" Odorous molecules are carried into the region by eddy currents, primarily on inspiration Stimulation of the olfactory mucosa may also occur on expiration It is possible that some of the contribution of the odor sensing system to the dimensions of taste occurs during expiration when food is being chewed

The receptor cells of the olfactory system which reside in the olfactory epithelium are relatively primitive Unlike many other receptor cells, they serve both as primary receptors and primary neural connections to the next higher level of the nervous system An illustration of the cells of the olfactory mucosa based on electron microscopic examination of this tissue is presented in Figure 8 125 Supporting cells, the sustentacular cells, mingle with the receptor cells The latter may be discriminated from the supporting cells by their longer projection beyond the limiting membrane of the epithelium, and by their relative lack of endoplasmic reticulum The enlarged terminal "rod" of each sensory cell supports between 6 and 12 cilia on its exposed surface in a sepal-like arrangement Microvilli are formed by the plasma membrane, and the cilia of the rods are enmeshed in these The cilia are bathed in a fluid secreted by Bowman's glands In addition to the columnar supporting cells and the terminal rod of the receptor dendrites, there are basal cells in the olfactory epithelium Trigeminal nerve endings have also been identified in this region The cilia can be shown to move, and their motion is enhanced when the mucal substance in which they are surrounded is washed away (Tucker, 1967) The cilia are apparently unnecessary for receptor function, however, and the significance of their number, their orientation, and their movement is unknown In the rabbit at least, it has not been possible to make any clear cut structural differentiations among the olfactory rods (de Lorenzo, 1963) Differentiations have been sought in the hope that they might provide clues to the nature of the discrimination process The only possible basis for classification is the fact that these terminals may contain either a relatively high concentration or a relative paucity of mitochondria

The primary receptor cells are bipolar cells, the axons of which are of relatively small diameter, of the order of 0 2 μ in the rabbit Individual fibers are gathered into small bundles of fascicles which conduct afferent signals upward to the olfactory bulb (de Lorenzo, 1963) Removal of the olfactory bulb in the rat results in complete degeneration of the olfactory neurons (Sen Gupta, 1967)

Electrical Activity of the Olfactory Mucosa. When the olfactory mechanism is appropriately stimulated it is possible to record a negative potential at the olfactory epithelium with a gross electrode (Ottoson, 1963a) This is presumably a reflection of local graded potentials within individual cells of a population of cells which are responding to the stimulation (Ottoson and Shepherd, 1967) This potential was reported by Ottoson in 1956 and is sometimes called the Ottoson potential (Fig 8 126) More commonly, however, it is known as the electro-olfactogram or osmogram (EOG) In as much as the small diameter of the individual fibers of the olfactory receptors made it difficult to record from individual units until very recently, the EOG has provided a useful index of the responsiveness of the olfactory system to stimulation More recently, however, it has been possible to record the pattern of spike activity in single units with microelectrodes (Gesteland et al , 1963) In the frog, unit responses were recorded with metal microelectrodes (Fig 8 127) The resting level of activity was found to be extremely low,

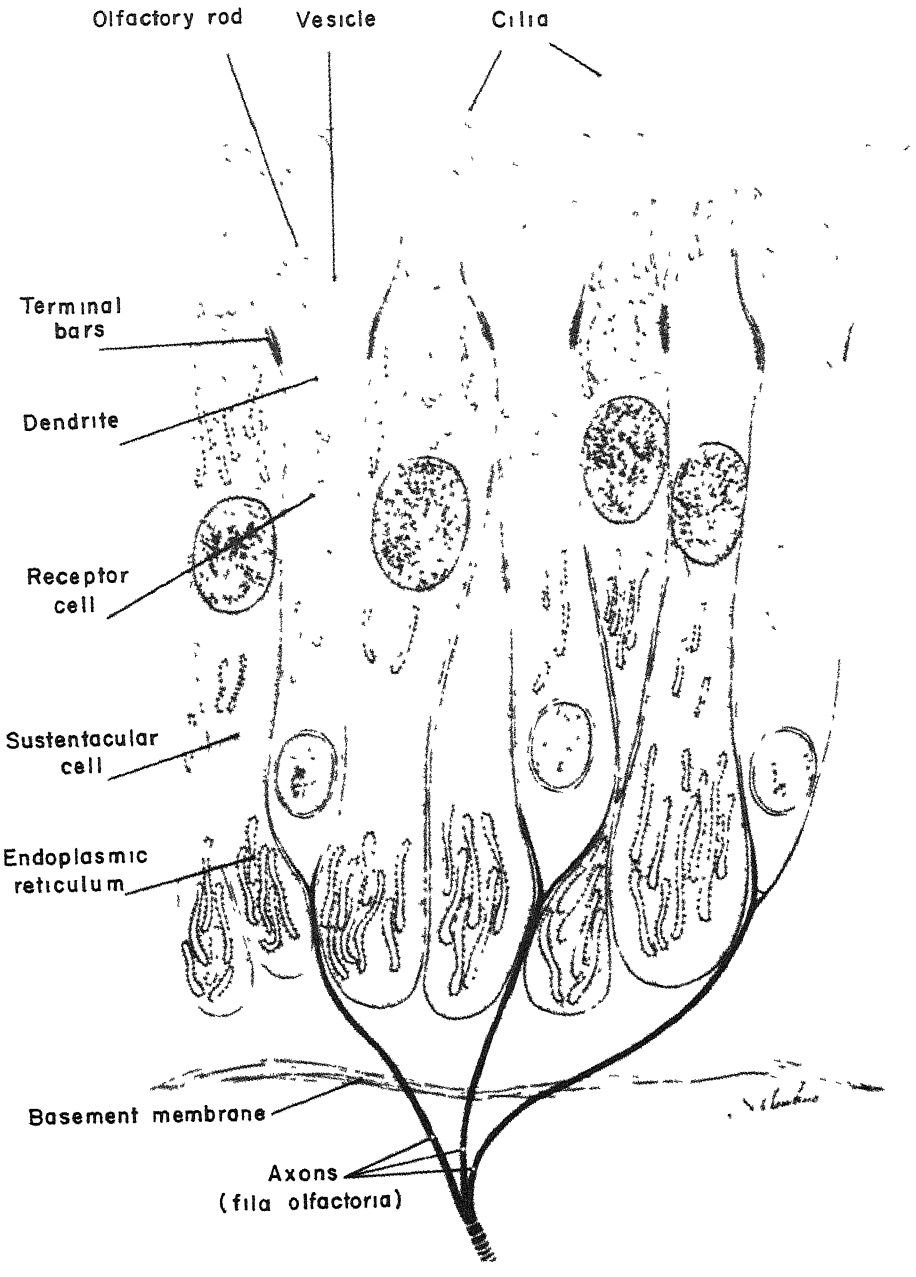

Fig 8 125 Olfactory mucosa showing the relationships of various cell types based on electron microscopic observations (de Lorenzo 1963)

and in many units, there appeared to be no resting level of activity at all On the basis of mode of response to different odorants, eight groups of units were identified from a large number of individual unit recordings These eight groups represented typical response patterns to the different stimuli There was considerable overlapping of response to different stimuli but, nonetheless, the patterns were considered sufficiently distinctive to permit such classification Bursts of spikes which lasted from 1 to 4 sec appeared at rates of up

to 20 spikes/sec Later work (Lettvin and Gesteland, 1965) confirmed the earlier conclusion that individual units within the olfactory epithelium are differentially responsive to different stimuli It appears, however, that the earlier eight classes which were distinguished may be too few In the more recent paper it is suggested that there are at least 10 different kinds of ordering of activity, and probably less than one million kinds of ordering Obviously, the authors are not yet willing to be very specific For any odor employed as a stimulus, it was always possible to find at least one unit stimulated to a high level of activity, and another stimulated hardly at all or possibly even depressed

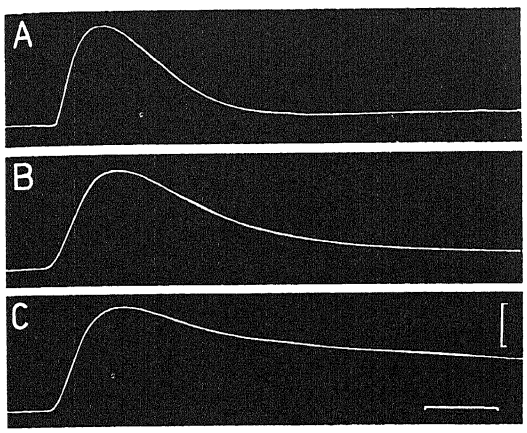

Fig 8 126 Electro-olfactograms (EOG) to different types of stimulation A amyl acetate B butanol C oil of cloves The vertical line represents 1 mv and the time bar represents a duration of 1 sec (Ottoson 1956)

CENTRAL CONNECTIONS IN THE OLFACTORY SYSTEM

Axons of the bipolar cells, whose dendritic terminals are the olfactory rods or primary receptors of the system, cross the lamina propria and join with other axons to form strands of some 20 fibers These ascend in grooves of the ethmoid bone, penetrating the cribriform plate enroute to the olfactory bulb The axonal terminations of these fibers consist of tufted filaments which synapse with the dendritic terminations of cells of the olfactory bulb These terminations are enlarged filamentous bodies known as glomeruli Connections may be with tufted cells, the cell bodies of which are somewhat superficially located, or with mitral cells whose cell bodies are deeper within the structure of the olfactory bulb Granule

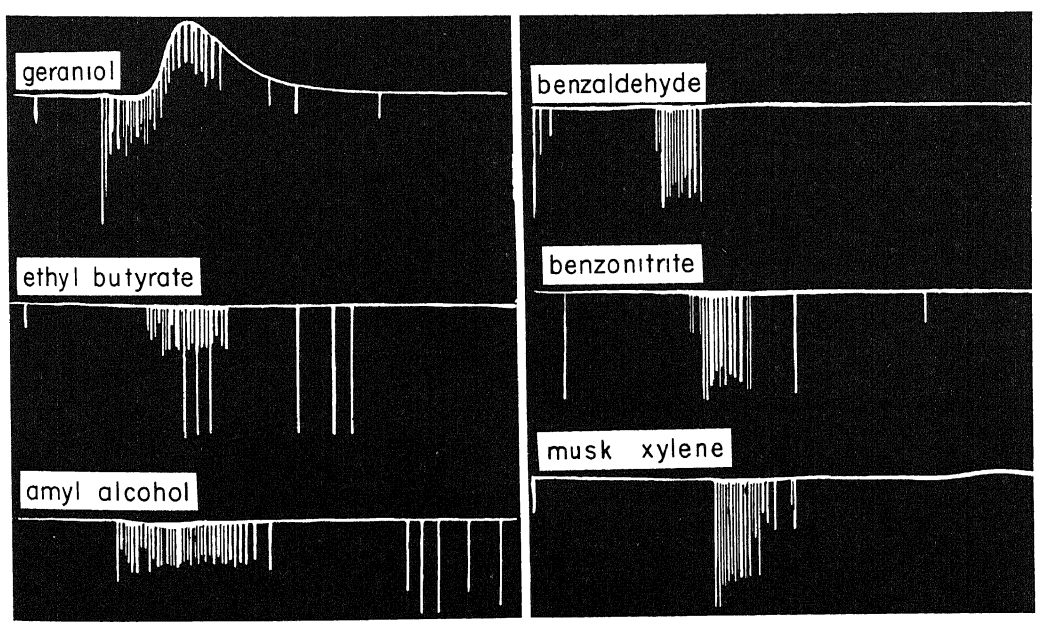

Fig 8 127 Impulse responses to geraniol ethyl butyrate amyl alcohol benzaldehyde benzonitrite and musk xylene All sweep lengths are of 10-sec duration The slow potential is discriminated only for geraniol the other stimuli being too small Several different units may be discriminated on the basis of amplitude of response (Gesteland et al 1963)

cells are located near the center of the olfactory bulb in the core white matter Early microscopic studies suggest that axonal branches from mitral cells reflect back upon the layer of synaptic terminations of the primary cells These cells may be responsible for inhibitory processes which have been observed in the olfactory bulb Connections have been reported between mitral and granule cells in both directions The action of mitral cells on granule cells appears to be excitatory, while the reverse relation results in inhibitory action (Rall et al , 1966) Fibers from tufted cells and from mitral cells project from the olfactory bulb, extensions of some of these fibers form the myelinated fibers of the olfactory tract Section of the olfactory tract results in the degeneration of fibers from mitral cells, but not of those from tufted cells This suggests that the mitral cells alone are the secondary neurons which send projections centrally from the bulb Fibers from the tufted cells may cross to the opposite side of this bilaterally symmetrical organ

Connections within the olfactory bulb as well as cross connections between the two hemispheres are relatively complex There appears to be a plexiform arrangement of fibers arising out of the olfactory epithelium and consequently no point-to-point correspondence between regions of the epithelium and the bulb itself For the rabbit, it has been estimated that there are approximately 1000 primary nerve endings/mitral cell (Rall et al , 1966) von Békésy has suggested that the interactions mediated by lateral interconnections of the two hemispheres provide an olfactory analog of the mechanisms of localization in hearing (1964a)

The electrical activity of the olfactory bulbs has been studied extensively by a number of investigators Adrian (1951) reported some stimulus specificity associated with different regions of the olfactory bulb Heptane and other related chemicals were found more effective in stimulation of the posterior regions of the bulb, while amyl acetate and related substances were more effective in the stimulation of the anterior region Thus, fruity substances are believed to be associated with anterior stimulation and oily substances with posterior stimulation Recordings were made extracellularly with microelectrodes The fact that there is some topological relation between the bulb and the olfactory mucosa, even though it is not a point-to-point relation, suggests a spatial organization of response properties at the level of the olfactory epithelium This work has been confirmed and extended by Mozell and Pfaffmann (1954) and Mozell (1958) The regional specificities were found to be maintained with variation in the concentration of the stimulating substances In more recent investigations of this problem with chronic implants in the rabbit, Moulton (1963, 1965) obtained results which lead to the conclusion that there is spatial and temporal patterning, but he was unable to make any generalization concerning the relative effectiveness of the different odorants employed in the stimulation of the various regions of either the peripheral epithelium or the olfactory bulb

The presence of efferent fibers which appear to regulate the level of response at the olfactory bulb serves to complicate the problem of understanding the olfactory mechanism (Cragg, 1962, Kerr and Hagbarth, 1955) Moulton (1965) was able to obtain much less variable responses from the bulb after sectioning of the anterior olfactory regions through which efferent fibers passed to the bulb Regulatory effects on the olfactory system may also be mediated by extrabulbar efferent pathways There are autonomic fibers which innervate the olfactory mucosa independent of any bulbar connections (Tucker and Beidler, 1956)

Classically, the central projections from the olfactory bulb have been assumed to go to the rhinencephalon, or "smell brain " It is now known that this region of the brain, the limbic region, is concerned to a much greater degree with emotional states and affect than with the processing of olfactory information The myelinated fiber bundle comprised of axons of the mitral cells makes up the olfactory tract which courses caudad under the frontal lobes Unlike any other major sensory pathways there is apparently no stage which passes through the thalamus Connections from the olfactory bulbs appear to be to the prepiriform area, to parts of the amygdaloid complex, and to the olfactory tubercle Contrary to earlier belief, there are no direct connections to the hippocampus or the septal area It also appears that, although they seem to be closely related in sensory experience, there are no significant cortical interrelations of the sensory systems for taste and smell

The olfactory bulb seems to have a promi-

nent role in a sensory discrimination of a nonolfactory nature It has been demonstrated that x-irradiation provides a very effective discriminative stimulus for the control of animal behavior In addition, x-irradiation may give rise to arousal from sleep or changes in the electroencephalogram (EEG) pattern (Kimeldorf and Hunt, 1965) The part of the body which mediates the response to such radiation has been localized in the rat to the olfactory bulb (Hull, et al , 1965, Dinc and Smith, 1966, and Brust-Carmona et al , 1966) Similar results have been found for the monkey (Taylor et al , 1968)

Studies of Olfaction

PSYCHOPHYSICAL EXPERIMENTS

Precise measurements of the stimulus quantity necessary for the induction of an olfactory sensation are quite difficult There is no generalized intensity dimension such as exists in the case of vision and hearing One can only deal with the concentrations of various chemical stimuli, each of which has its own unique accompanying qualitative sensation A variety of techniques has been developed for the measurement of olfactory thresholds One of the first devices used for such purposes was the olfactometer of Zwaardemaker (1925) This consisted of a glass tube inserted into another tube which was porous and impregnated with an odorous substance By varying the extent to which the smaller tube was inserted into the larger one it was possible to vary the length of the larger tube through which the inspired air was drawn before it reached the nostrils This provided a crude control over the concentration of odorous material in the inspired air Zwaardemaker was able to utilize this device for the comparative evaluation of the thresholds of a number of materials

Much more sophisticated devices have been developed since this early technique was employed Elsberg and Levy (1935) utilized a device in which the amount of stimulus-bearing air was controlled The vessel containing the stimulating substance was compressed and a stimulus was presented in a controlled puff to the subject One problem with this procedure is that the sudden application of pressure to the nostrils provides additional sensory stimulation in a nonolfactory dimension It is possible that the active sniffing of a subject is a better procedure Moreover, the control of this procedure from time to time and between individuals is anything but exact Rather complicated olfactometers have been developed in recent years (Johnston, 1953) These provide for the mixture of known concentrations of odorous material with purified air containing controlled amounts of moisture (Fig 8 128) Rotameters permit the precise control of the mixture of various components Subjects may be trained to open the nasal passages so that air is permitted to flow through the nose and down into the mouth continuously A controlled volume presented at a specific flow rate may be employed A normal sniff is probably equivalent to between 50 and 100 cm^3 and some amount in this range may be adopted as a standard

It is extremely important to control environmental conditions, it was demonstrated long ago that prolonged exposure to relatively pure air prior to the measurement of threshold results in a significant lowering of threshold, by 25% on the average for a large number of substances (Komuro, 1921) An elaborate shielded enclosure has been devised for the complete control of the ambient air (Foster et al , 1950) Studies are undertaken in which stimuli may be presented to one nostril or to two nostrils, or different stimuli may be presented on the right and the left side at the same time

As indicated above, the threshold concentrations required for the detection of odors are exceedingly small Even so, the number of molecules in a cubic centimeter at these low concentrations may be rather large Neuhaus (1954) has estimated that at threshold there are 4×10^8 molecules of ethyl mercaptan in

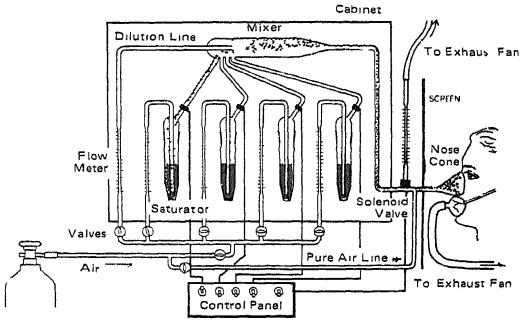

Fig 8 128 An olfactometer which permits the mixture of odors in precise proportions prior to their delivery to a nose cone for sampling Air may be bubbled through liquids to pick up odorous molecules and then diluted with pure air or mixed with air carrying other odors (Amoore et al 1964)

each cubic centimeter of the inspired air It is of interest to consider the number of molecules and receptors which contribute to the detection of odor Computations made by DeVries and Stuiver (1961) suggest that on the order of eight molecules must stimulate each nerve ending, and 40 nerve endings must contribute to the neural activity which is transmitted centrally before an olfactory sensation will arise The large individual differences in structure of the nasal cavity make such computation highly approximate at best

No measure of olfactory sensitivity is any better than the care which has been taken in the purification of materials employed for the purpose Wright (1964) has shown that odors associated with some substances may disappear when the substances are utilized in a highly purified form

The measurement of olfactory thresholds has been shown to bear some relation to tumors with a highly specific location If a tumor is located in the lower region of the frontal lobe, thresholds for odorous substances may be raised and, following exposure to odorous materials, a longer time may be required for recovery of sensitivity than is true for the normal In certain cases of hysteria, with increased intracranial pressure, or in the initial stages of the action of cocaine, olfactory thresholds may be lowered

As is true with all sensory dimensions, an increase in the background level of stimulation is associated with an increase in the amount of the increment which can be detected against the background Direct proportionality of the increment to the background holds over a limited range in many sense modalities and, although only an approximation, is known as the Weber-Fechner "Law " This is also true in olfaction Here, as with other senses, the ratio is relatively higher at low levels and tends to reduce as the background level of stimulation is increased, leveling out at the higher concentrations, and then increasing again The concentration of the increment must be from two times to one and one-third times that of the background to be detected The discrimination sensitivity in olfaction is, thus, not very keen

Adaptation of the olfactory mechanism occurs with prolonged exposure to odor Unlike the visual or the auditory sense, the olfactory sense frequently adapts out entirely That is to say, when it is maintained in a given concentration, a specific odorous material may become completely undetectable after an appropriate length of exposure Complete adaptation to a substance called cumarin in a 0 2% aqueous solution occurs in approximately 2 min Threshold for detection of the chemical following adaptation may be elevated for as long as several hours Adaptation effects may include a central component (Moulton, 1963)

The adaptation is a selective process That is, adaptation to one substance does not necessarily elevate threshold for other substances This suggests that whatever the basis of adaptation, it involves receptors or pathways which are themselves qualitatively selective in function It is obviously not some kind of generalized "fatigue " In some instances, the qualitative aspect of sensation changes with adaptation For example, during the process of adaptation, the odor associated with ionone changes from that of cedarwood to the faint odor of violets, while the odor of nitrobenzol changes from that of bitter almonds to a tarry smell (Geldard, 1953)

One approach to the study of the olfactory process might be to determine very carefully the way in which thresholds for the detection of various substances are elevated by adaptation to other substances This would permit a kind of functional linking of various compounds in terms of their probable action on the same receptor sites within the olfactory system Smelling of camphor to the point of adaptation results in the elevation of threshold for a number of other substances including oil of clove, oil of eucalyptus, and ether, but does not influence the threshold for benzaldehyde Adaptation to benzaldehyde does not influence the threshold for camphor It seems reasonable to assume that these substances are not interacting with the same sensory terminations in the olfactory epithelium

Another aspect of odor which might provide useful clues as to the nature of the olfactory process relates to the way in which different odors combine Such information is almost entirely subjective and must, therefore, be qualified accordingly, but it would seem that there are at least four possibilities as to the method of combination odors characteristic of two substances may fuse into a new and "unified" odor which may have recognizable aspects related to either or both of the components, the odor associated with the combina-

tion of two substances may be recognizable as a blend of the two much as a combination of notes, there may be an alternation of ascendence of one or the other component when two substances are mixed with respect to the prevailing sensation of odor, and one component of a pair may completely mask any response to the other component There has been some question as to whether a fifth possibility may be entertained, that is that two odors in combination may completely neutralize each other According to Zwaardemaker (1925), this is a possibility but the components must be relatively weak in concentration Others have argued against the possibility of any physiological combination which results in neutralization (Henning, 1924)

The highly subjective nature of odors and their tremendous range of qualitative variation limits the way in which they may be studied with animals The obvious approach is one of determination of threshold for various materials, there is a wealth of literature on this particular subject (Wright, 1964) It is clear that many animals are far better endowed than is man for the detection and discrimination of odors For certain substances, such as acetic acid and butyric acid, for example, dogs are capable of detecting concentrations lower than that required by man, by as much as a million to a hundred million times There is also evidence that the qualitative range of discriminable odors is appreciably broader for some animals than it is for man The survival value of the olfactory process is obviously of greater significance to these organisms than in the case of man Actually, the olfactory mechanism of man himself is probably far more sensitive and selective in its discrimination capacity than is necessary in a civilized world There is undoubtedly a great deal more information available to us in the olfactory realm than we utilize or than we need Such information, however, may have been of the highest significance for our forebears

Just as color blindness has provided us with some important clues as to the nature of the color discrimination process, so a comparable condition in olfaction may afford clues as to the nature of olfactory discrimination This is the condition of selective anosmia Some persons show a selective loss for the detection of odors characteristic of specific substances One of these is hydrogen cyanide This has long been associated with some form of genetic determination, although this has recently been called in question (Brown and Robinette, 1967) Selective loss of sensitivity may mean a genetically determined lack of a specific type of receptor or a unique chemical balance which precludes the detection of certain odors or any of a number of other possibilities The systematic study of the condition would appear to be of potential value (Amoore et al , 1968) Guillot (1948a and b) and LeMagnen (1948) have demonstrated that some individuals have specific anosmias for certain musky odors and not for others This is of particular significance in that many investigators have argued for muskiness as one of the primary odor qualities (Amoore, 1952, 1963)

One interesting characteristic of odors is the fact that their strength does not appear necessarily to be related to threshold (Wright, 1964) An odorous substance with an exceedingly low threshold (musk or vanillin, for example) may never have an overwhelmingly strong smell even at very high concentration On the other hand, a substance with a significantly higher threshold, such as ethyl mercaptan, becomes overwhelmingly strong as the concentration is increased A method of studying this phenomenon has been provided by Kruger and his colleagues (1955a) They have developed a scale of odor strength based on varying concentrations of n-heptonal The odor of this substance is quite strong when it is at high concentration It may be diluted with an odorless solvent such that its strength can be adjusted down to a minimal level By selecting appropriate dilutions, a scale of as many values as desired may be created Other odors can then be matched against the standard scale by observers who have been trained in its use Such a procedure permits a kind of quantification of odor strength at levels well above threshold The relative intensities of the aliphatic alcohols for human subjects have been examined with this procedure by Kruger et al (1955b) Their results indicate a tendency for the strength of an odor to decrease as molecular weight exceeds a certain amount As mentioned above, this is associated with a reduction in the volatility of the substance When various members of the aliphatic series were corrected to have equal vapor pressure, it was found that the heavier molecules had slightly higher odor intensities Of course, the method becomes inapplicable

when the extent of dilution of the simpler molecules becomes so great that the dilute solution retains no odor at all

This method may be of particular value in studying the substances with different relations between threshold and strength as concentration is increased Odors with low threshold which do not increase rapidly in strength as concentration is increased are said to be "insistent" odors

Theories of Olfactory Discrimination

There is substantial and convincing evidence that the qualitative differentiation of olfactory sensation depends upon the pattern of response in specific neurons which make up the olfactory nerve and the olfactory tract The way in which encoding takes place at the olfactory epithelium remains a mystery Dimensions of olfactory sensation are complex and have not been shown, conclusively, to bear any clear-cut relation to physical characteristics of the stimulus There does not seem to be anything analogous to the relation between frequency or frequency complex and tone or tonal quality in hearing, or hue and wavelength distribution in vision There is undoubtedly a relation between the intensity dimension of smell and the rate of activity in the neural substrate which mediates this sensation (Adrian and Ludwig, 1938), but the more interesting questions relate to those aspects of the stimulus and those aspects of the receptor mechanism which determine the qualitative nature of an odor

One of the earliest suggestions as to a mechanism which might explain olfactory phenomena was proposed by Lucretius (Amoore, et al , 1964) He suggested that the airborne particles which carry scent have unique shapes which correspond to sites within the olfactory mechanism These were assumed to vary with respect to shape, and hence, to be ideally suited for the trapping of specific kinds of molecules Thus, depending upon the specific sites in which molecules are entrapped, different odorous qualities may be experienced Theories of this sort were surveyed by Moncrieff (1951) Amoore (1952), after a detailed search of the literature on olfaction, catalogued odorous substances according to the language used to describe the odors which they produced He found that a large majority of substances could be included in just seven categories and that each of these had many more substances associated with it than did the other categories which were identified in his survey His supposition was that these most frequently occurring sensory qualities might correspond with anatomical receptor primaries The next stage of his undertaking was to look for some characteristic which those substances having a common capacity for the stimulation of odor might share with respect to their chemical or physical nature His conclusion was that the shape of the molecule was in most instances of a similar form for materials with similar odor-producing capabilities Two of the odor qualities apparently depended upon the electrolytic characteristics of the substance rather than molecular structure Amoore, therefore, devised receptor sites in five unique configurations based on the form of molecules which produce a characteristic odor Early reports of discrimination among neural units of the olfactory mucosa (Gesteland et al , 1963) were interpreted by Amoore in support of his theory (Amoore, et al , 1964) He has evaluated the adequacy of the physical receptor sites he devised, in terms of how nearly they are filled by models of the molecules to which they are presumed to play host, by actual physical test of the extent to which they fill the volume of the theoretical sites The results of this evaluation showed the sites to be rather unsatisfactory in terms of the efficiency with which they could encompass the volume of molecules with similar odor characteristics He has, therefore, abandoned his earlier theoretical site designs (1965), but has shown a definite correlation between the character of an odor and an index of the geometry of the molecule based upon three orthogonal projections of its spatial configuration There appears to be some significance to molecular shape in the determination of odor, but the exact relation of shape to some characteristic of the olfactory receptors is still unknown Amoore's original seven primaries seem to represent an oversimplication of the situation

As mentioned earlier, odorous substances tend to be highly absorbent in the infrared region of the spectrum One theory of olfactory discrimination (Beck and Miles, 1947) held

that local cooling resulting from the absorption of heat by odorous molecules provides a basis for discrimination A serious difficulty with this theory arises out of the fact that certain substances with identical infrared absorption spectra have different odors In addition, attempts to duplicate early experiments which supported the theory have proven unsuccessful (Johnston, 1953) A theory based on the supposition that there is a variety of different enzymes which may be selectively inhibited by different odorous substances was proposed by Kistiakowski in 1950 A small amount of odorous material might block an enzyme reaction and result in the accumulation of a large amount of substance which could provide stimulation of selected nerve endings Objections to the theory have been based on the fact that many optical isomers which should react differently with enzymes provide the same odor (Wright, 1964) It is also argued that too large a number of different receptors would be required for the system and that the temporal response characteristics of the olfactory sense, which are relatively rapid, are incompatible with a primarily chemical basis of detection

The theory might be useful if the olfactory epithelium could somehow accomplish a preliminary discrimination of substances based on their physical or chemical properties This would reduce the large number of different enzyme classes necessary for the range of odorous qualities which can be discriminated Patterning of the distribution of odorous stimuli over the olfactory epithelium may be selective by reason of some sort of chromatographic process (Mozell, 1966) Davies (1965) has argued for variation in the fluid properties of receptor cell membranes as a basis for receptor selectivity Other theories have been proposed based upon the charge-transfer effects between carotinoid pigments in the receptor membrane and specific odor-bearing molecules (Moulton & Beidler, 1967, Rosenberg et al , 1968)

Some years ago (Dyson, 1937), it was proposed that the characteristic resonant frequencies of specific molecules might provide a basis for the determination of the odors which they produced The "Raman effect" provides a method of determining the characteristic vibration frequencies of specific molecules Wright (1964) has argued that vibrational frequencies, expressed in wave number, are not associated with sufficient energy to be of any significance for a mechanism of smell discrimination, unless the wave number is 200 or less Early criticisms of Dyson's theory were based on noncorrespondence of very much higher wave numbers for molecules producing similar odors Recently, Wright and his associates (Wright et al , 1967) have concluded that the frequency components of the activity induced in the olfactory bulb by odorous stimuli are correlated with molecular frequencies of the molecules which constitute these stimuli The results cannot be considered conclusive, however, since the correlation is far from complete when all frequency components are considered

Although there are intimations of progress, the question of how the olfactory mechanism discriminates qualitative differences in odor is far from resolved It is fair to say that different neural pathways and patterns of response among populations of pathways are involved in the qualitative discriminations of odor, but the precise way in which the initial discrimination is made at the primary receptor site is unknown Future research must include a comparative evaluation of electrophysiological studies, psychophysical studies based on threshold and qualitative discriminations for a variety of stimuli alone and in combination, and the individual differences represented by selective anosmias which may be genetic in origin

7 / TOUCH, TEMPERATURE, AND PAIN SENSITIVITY

The successful adaptation of an organism to its environment requires the continuous derivation and processing of a variety of information Although the most richly varied of the sensory dimensions may be vision and hearing, those treated in this chapter are nonetheless important for the maintenance of the health and welfare of the organism Receptors in the skin and other parts of the body which make contact with the external world, including the tongue and the teeth, provide a basis for constantly monitoring the compatibility of the environment

Elaborate mechanisms for the regulation of body temperature are dealt with elsewhere, but without the additional mechanisms which depend upon voluntary actions mediated by conscious response to sensory stimulation, it would be impossible for man to maintain regulation of body temperature over the range of environmental temperatures in which he is able to function The rate of his voluntary activity and the nature of his clothing are important factors which are controlled by conscious processes

Protection of the organism from injury requires information as to the nature of objects and surfaces with which the body may come in contact Such characteristics as hardness and softness and abrasive qualities may not be discernible visually and may require exploratory physical contact The manipulation of objects depends on information as to the nature of the contact made by the body, usually the hands or feet, and changes in pressure associated with changes in the tension of muscles controlling the fingers or perhaps the jaws Feedback systems involving muscle sensors permit highly refined control, but the augmentation of this system by tactual sensitivity is essential for proper function Motor control of the body depends to a significant degree on information based on tactual sensation derived from contact with the surfaces on which the body may be lying, sitting, standing, or walking

Physical contacts may be destructive Deformation of tissue at too high a rate or to too great an extent can cause injury The same is true of objects at a high temperature or, less frequently, at a very low temperature, sources of thermal radiation, and chemical agents Virtually any agent capable of causing tissue damage signals the organism by stimulating receptors for pain There are some exceptions, such as ultraviolet radiation and ionizing radiation It is only in the very recent history of man that ionizing radiation has constituted a significant hazard and it is perhaps for this reason that no "counter measures" have evolved As noted in an earlier chapter, there may be some possibilities for direct detection of ionizing radiation, mediated by the olfactory bulb

The deep pain which is signalled by receptors in the internal organs is qualitatively different and the sensory system which mediates this response serves a different purpose Ideally, its function may be to impose restrictions on activity during a period of recovery from injury In extreme conditions, however, such pain may be completely nonadaptive

In addition to its role in the regulation of behavior and survival, the sense of touch may play a significant role in communication An excellent direct example is the reading of Braille by the blind, a more subtle example is the nature of the communication process involved in the character of a handshake or any physical contact between individuals The sense of touch plays an extremely important role in the communication between individuals which precedes sexual activity in all of the higher organisms

In relatively recent years, considerable effort has been devoted toward the use of the tactual sense as a means of substituting for vision in the case of the blind A large matrix of stimulators may be excited by a system which involves a television camera It has been demonstrated that, with sufficient practice, blind

individuals can do a remarkable job of discriminating the nature of objects in the real world with such a system (Collins and Saunders, 1970)

The Sense of Touch

The sense of touch is primarily a cutaneous sense, although it is usually considered to include the touch receptors within the mouth, particularly on the tip of the tongue, and the receptors located in dermal tissue, tendons, the periosteum, and other deep seated structures which respond to pressure

THE STIMULUS

The sensory endings for touch are known to respond to uneven or nonuniform pressure which results in deformation of the skin or movement of the hairs which grow out of the skin Sensitivity to touch varies in different regions of the body, but may require only very slight deformation or barely perceptible deflection of a single hair on the surface of the body A wisp of cotton drawn over a hairy surface or even over bare skin is sufficient for stimulating the sense of touch A technique for measuring the relative sensitivity of the various regions of the body's surface to touch was developed by von Frey (1919) A series of hairs, varying in diameter, was graded in relation to the pressure required for bending the hair when it is brought in contact with a surface Threshold for touch may be determined in terms of the pressure required to bend a hair Surfaces of the body which are sparsely covered with hair tend to be more sensitive to direct contact Shaving the hair from a hairy surface results in reduction of sensitivity to touch

Minimum pressures required to elicit the sensation of touch vary by a factor of more than 20 to 1, depending on the region of the body considered The nose, the lips, and the tips of the fingers require only 2 or 3 g /mm ^{2} Higher pressures are required on the backs of the fingers, the upper arm, and the inner surface of the thigh Progressively higher pressures are required on the back of the hand, the calf, the shoulder, the abdomen, the front of the leg, the sole of the foot, and the back of the forearm A pressure of nearly 50 g /mm ^{2} is required on the loin It is evident that those portions of the body's surface which are more likely to be involved in contact which will provide information have a lower threshold

RECEPTOR ORGANS FOR TOUCH

In the skin there are some relatively elaborate sensory receptors which undoubtedly play a significant role in touch There are also undifferentiated nerve endings which are involved in tactual response (Fig 8 129) Unfortunately, it has not been possible to find clear-cut functional differences associated with the anatomical differences among the various receptor types Nonspecialized receptors which cannot be distinguished anatomically may mediate qualitatively different responses, i e , pain and

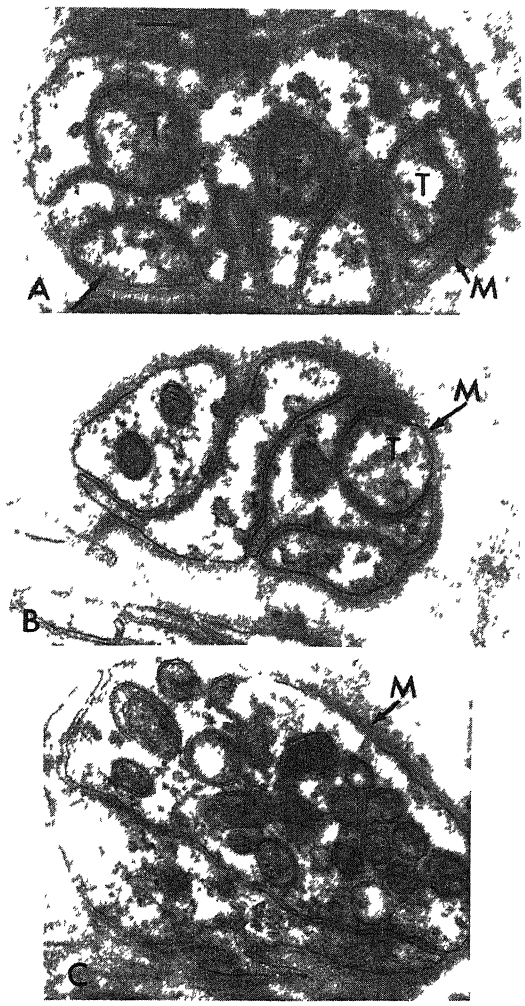

Fig 8 129 Free nerve endings in the tips of dermal papillae of the human digital skin Perineurial sheaths have been lost but Schwann cell coverings and the basement membranes (M) are retained Three terminal branches (T) are shown within one Schwann cell body in *A* A single nerve terminal (T) is shown in relation to a cluster of Schwann cells in *B* An end bulb is shown in *C* with an accumulation of mitochondria varying in size and density (× 51 000) (Cauna 1968)

temperature as well as touch The specialized receptors include Meissner's corpuscles (Fig 8 130) which are found in abundance in the hand, the foot, the nipple, the lips, and the tip of the tongue, Merkel's disks (Fig 8 131) found in the fingertips, the lips, and mouth, and basket-like terminations which surround hair follicles Structures which look like Merkel's disks have been found in epidermal domes (Fig 8 132) which appear to be specialized receptor regions in the skin (Iggo, 1966) Similar structures have been identified in other tissues (Cauna, 1966) Some of these receptors are illustrated schematically in Figure 8 133 There is evidence that the cells which comprise nerve endings change relatively frequently during the life of the individual (Cauna, 1966) This continuing renewal of receptor tissue is also characteristic of the gustatory and olfactory systems

It is obvious from the foregoing that the innervation of the skin of various regions of the body differs with respect to the sense of touch Even in a relatively homogeneous region, such as the back, there are differences. Localized regions, or spots, may be found which are more sensitive to touch or to temperature or to pain Responsiveness to these qualitatively different dimensions of stimulation is not homogeneously distributed

Fig 8 131 Two Merkel s disks in the deepest epithelial cell layer of an Eimer s organ in the tip of the mole snout Merkel s disks are seen directly below the more darkly stained epidermal cells (Quilliam 1966)

Receptive Field. The concept of the *receptive field* was conceived by Sherrington (1906) to describe the selectivity of response of an organism to tactual stimulation. Certain reflexes may be elicited by touch It is not necessary to stimulate one highly specific point, rather, a region may be stimulated and the reflex response will follow For a given reflex, the region in which stimulation will elicit the char-

acteristic response is known as the receptive field for the reflex Sizes of receptive fields vary with the region of the body and with the specific type of reflex investigated The results will differ dependent upon the qualitative nature of the stimulus

Functional Differentiation of Mechanoreceptors Two classes of receptors that respond to touch have been identified The first responds with impulse discharge for a period of only a few hundred milliseconds and then adapts, even though the tactual stimulation is sustained They have a relatively low thresh-

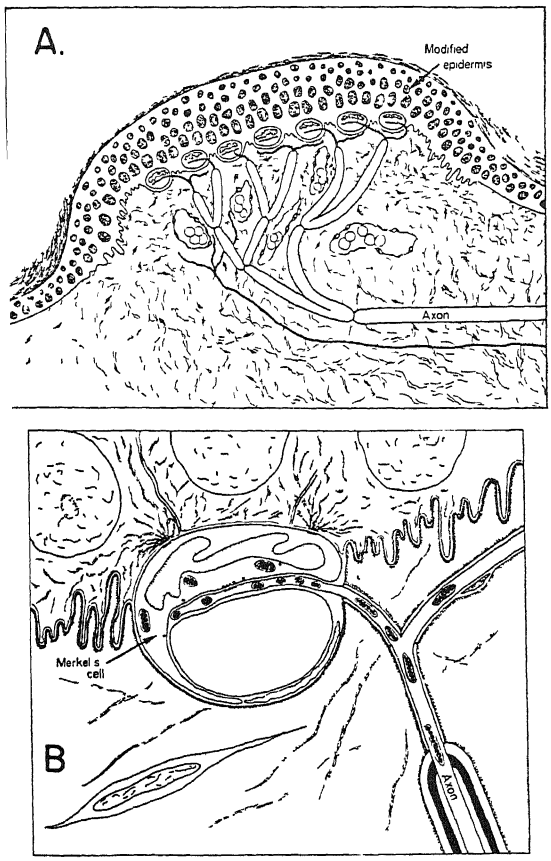

Fig 8 132 *A*, cross section of an epidermal dome with layer of nerve endings just inside the basement membrane Endings are derived from a single myelinated axon *B*, detail of the Merkel s cell at one of the nerve endings (Iggo 1966)

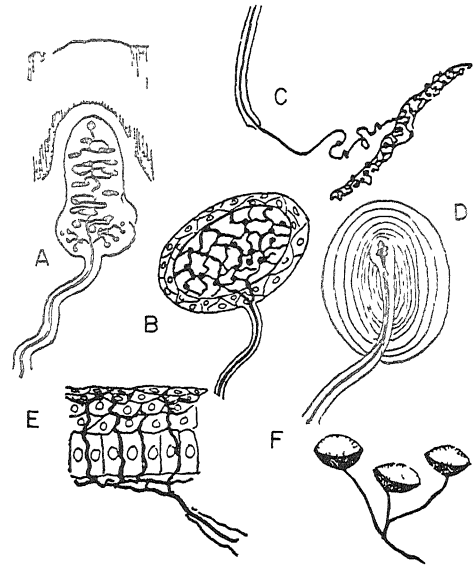

Fig 8 133 Various types of cutaneous receptors A Meissner s corpuscle (touch) B Krause s end bulb (cold) C Ruffini s end organs (warmth) D Pacinian corpuscle (deep pressure) E bar nerve endings in the cornea (pain) F Merkel s disks (touch) (Bainbridge and Menzie 1925)

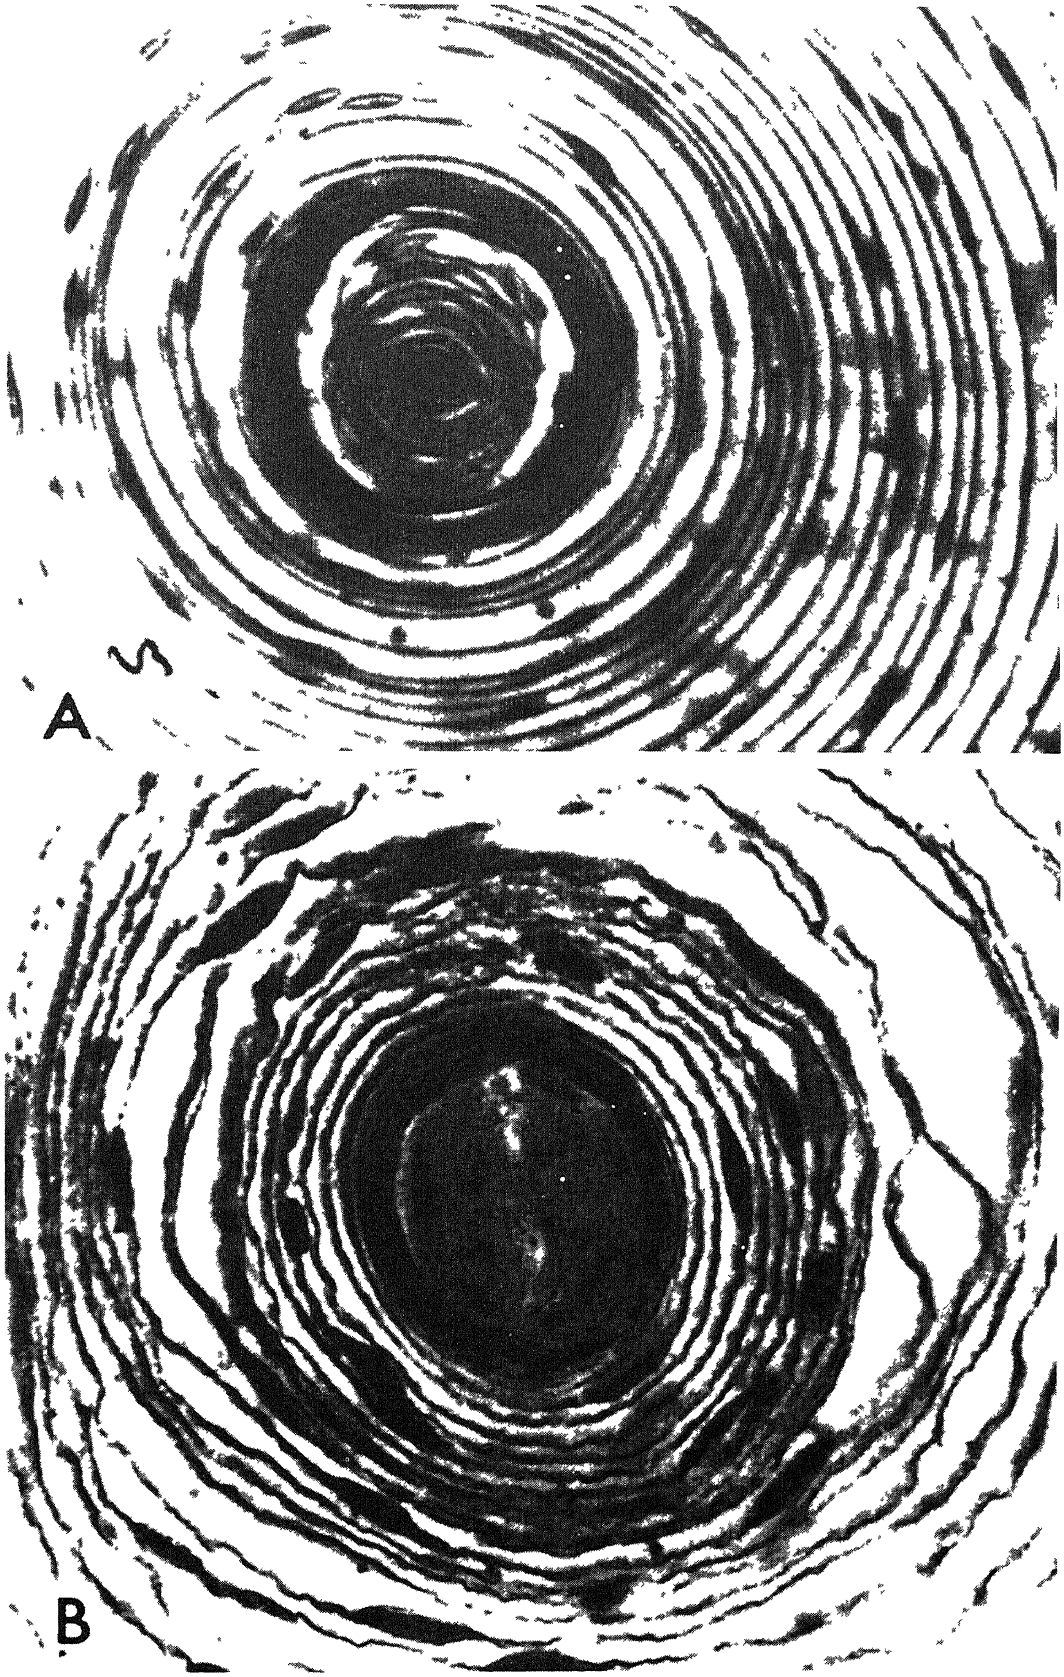

old, and are associated with receptive fields of as large as 5 cm ^{2} for a threshold level of stimulation These receptors are apparently served by myelinated fibers of up to 10 μ in diameter

Rapidly adapting units are found in nonhairy skin such as the footpad of the monkey These also show a discharge frequency which is relatively independent of the stimulus displacement Pacinian corpuscles (Fig 8 134) are associated with rapidly adapting responses to mechanical stimulation and may mediate this type of response when hair follicles are not involved They have also been associated with "deep touch"

The second type of receptor responds initially with a burst of activity and then adapts to a lower, sustained level of discharge This is sustained so long as the stimulation is continued for up to 5 min or even longer Recently, Iggo (1966) has associated the rapidly and slowly adapting receptor processes with specific anatomically defined afferent units

Fig 8 134 *A* unstained osmium-fixed transverse section of a cat Pacinian corpuscle as viewed by interference microscopy (× 750) The axial nerve terminal is oval in cross-section

B transverse section through a denervated Pacinian corpuscle of cat showing about 25 lamellae of the outer zone (× 900) Loss of circularity in the concentric outer lamellae and an apparent increase in the size of the lamellar nuclei are attributed to formol fixation and silver staining (Quilliam 1966)

A
B

He has associated the rapidly adapting receptors with the hair cells and divides these into three types The most sensitive are type D, characteristic of down hairs Their receptive fields are up to 2 cm ^{2} in area, and hence, many hairs must be capable of triggering a receptor response which converges on a single neural pathway It is probable that divergent connections also exist

Type G follicle units are those associated with "guard" hairs Ten or more of these hairs may be connected to a single neuron and in the 2-cm ^{2} area in which they are located other hairs will be connected to other neurons A kind of specialized guard hair termed a tylotrich follicle is found fairly commonly in the rabbit The type T-unit consists of an efferent neuron supplied by from 3 to 10 of these specialized guard hairs Each of the follicles is surrounded by a large venous sinus Electrophysiological studies of the monkey suggest that most of the rapidly adapting units found in this animal fall into the D and G classes The rate of discharge which occurs when a hair is bent apparently has little relation to the extent of bending When a threshold amount of bending has occurred, the discharge follows and if the hair is then maintained, perfectly undisturbed, in a fixed position, the unit adapts More rapid bending to a greater position of deflection serves only to reduce the latency of response The duration of response may be influenced by the number of hairs which are stimulated but rarely lasts much longer than 100 or 200 msec

The discharge of the slowly adapting units is very persistent In addition, the frequency of discharge varies with the amplitude of stimulation, the greater the displacement of the skin, the greater the discharge frequency Iggo has identified two types of slowly adapting units in hairy skin of the cat, rabbit, and monkey *Type I*, may produce a burst of impulses at rates in excess of 1000/sec when a smooth probe is drawn across a hairy skin surface This is a much higher discharge frequency than ever found with hair follicle units This type of response has been associated with the dome-shaped elevations of the skin which appear to contain Merkel cells as illustrated in Figure 8.132 The frequency of discharge increases with the amount of displacement of the tissue A mechanical stimulation of short duration, 1 or 2 msec, may cause a discharge of impulses which will last for as long as 10 msec For a fixed amount of displacement, the frequency of discharge is directly proportional to the displacement amplitude Similar results have been reported by Werner and Mountcastle (1968) for one class of receptors The type I units have a highly localized response and are relatively insensitive to lateral stretching of the skin They are normally quiescent at temperatures between 30° and 35° C in the absence of mechanical stimulation

Another differentiation in the nature of the response of tactual receptors relates to their ability to summate over time and area Pacinian corpuscles have been associated with responses which may be increased in magnitude by increasing either the duration or the area of stimulation There are other receptors which mediate a much more sharply defined response in both space and time (Verrillo, 1968) The latter are probably associated with the rapidly adapting receptors described above

The second class of slowly adapting receptors, *type II*, have a regular resting discharge in the absence of any mechanical stimulation When stimulation is applied, the initial response is of lesser amplitude than that of the type I units There is a reduction from the initial level following an adaptation period of several seconds, and with sustained stimulation a sustained level of discharge higher than the resting level may be measured These units are quite sensitive to lateral stretching of the skin So far, it has not been possible to associate these units, identified electrophysiologically, with anatomical receptor types Mountcastle and his colleagues (Werner and Mountcastle, 1968) have found some interesting differences in the relation between amplitudes of tactual stimulation and the response discharge frequency Some units have been observed (Fig 8 135) which show a linear relation between discharge frequency and tissue displacement Others show a linear relation between the logarithm of the response and the logarithm of the stimulus The slope of this linear relation is in the neighborhood of 0 5 and the response may, thus, be interpreted as a power function of stimulation with an exponent of 0 5 The linear relation referred to above is, of course, also a power function with an exponent 1 An interesting finding is that the results of scaling studies of tactual stimu-

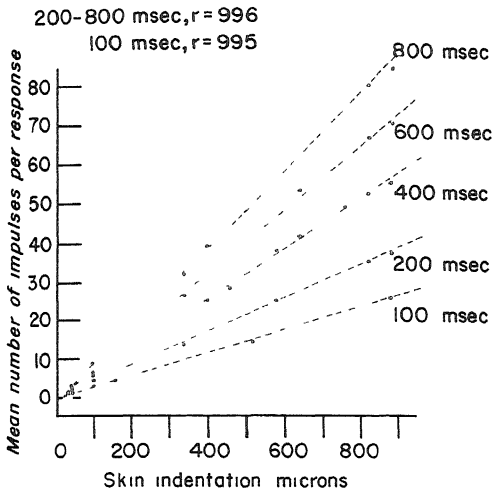

Fig 8 135 Number of impulses per response as a function of the depth of skin indentation for each of five observation times beginning at stimulus onset Recording from a single afferent fiber of the radial nerve of the Macaque Stimulus applied to the hand (Werner and Mountcastle 1968)

lation in human subjects reveal a functional relation between the magnitude of the stimulus and the scaled value, which is similar in form to the electrophysiological function derived from monkeys when the same region of the skin is stimulated

PERCEPTION OF TOUCH

Touch Localization. The location on the skin at which a tactual stimulus is applied can be identified fairly accurately by a human subject The accuracy varies, of course, with the region of the skin involved There is not a direct correspondence between the accuracy with which a point of stimulation may be localized and the minimum threshold for detection of stimulation The spatial relations among tactual receptors are obviously preserved in projections to the somaesthetic cortex, and there is some correspondence between localization accuracy and sensitivity The lips and the fingers, for which the tactual threshold is low, also permit highly accurate localization

The Two Point Threshold. A kind of discriminative localization threshold is provided by the test of the two-point threshold Two blunted compass points may be applied to the skin in various regions of the body The separation of the points may be varied in order to determine the minimum separation necessary for the subject to perceive the stimulus as two discrete points In such measurements, the subject is never aware as to whether the actual contact will be made by one point or two The experimenter is, thus, provided with an objective measure of the accuracy of the subject's report As one might expect, the minimum detectable spacing of two points is closely associated with the localization accuracy for various regions of the body's surface Two points may be discriminated as such when separated by only a little more than 2 mm at the fingertips, while a separation of as much as 6 or 7 cm may be necessary on the skin of the middle of the back, the upper arm, and the thigh

Localization accuracy may prove a useful basis for clinical diagnosis Certain cortical lesions are associated with a systematic displacement of the point associated with stimulation from the point actually stimulated on the same side of the body Certain forms of hysteria may be accompanied by a localization at a corresponding point on the opposite side of the body

The sense of touch is not restricted to receptors located in the skin So-called "deep touch" might more properly be called a response to pressure This is believed to be mediated by Pacinian corpuscles which are located in the dermus, tendons, periosteum, and other deep-seated structures

NEURAL PATHWAYS WHICH MEDIATE RESPONSES TO TOUCH

In the long ascending pathways of the spinal cord which conduct afferent signals from the skin and other parts of the body to the brain, there is a tendency for those fibers which mediate qualitatively similar responses to be grouped together Fibers from the skin and those from receptors located in deeper tissue may be located in the same portion of the ascending column when they carry information of a similar quality, such as touch The dorsal column-medial lemniscal system conveys information concerning the location and the nature of tactual stimulation, as well as its temporal variations It thus, appears to subserve precise discriminative functions The spinal thalamic system within the anterolateral tracts appears, on the other hand, to be more concerned with general aspects of sensation This tract has been associated with infor-

mation concerning the nature of the organism independent of the external world, although this kind of distinction is certainly not always valid Components of the spinal thalamic system project on the reticular formation in the medulla and the midbrain, as well as upon the intralaminar nuclei of the thalamus It is, thus, reasonable to associate it with arousal and vegetative processes (Mountcastle, 1961)

Projections on the somatic areas I and II of the cortex cannot be clearly differentiated, although there is a tendency for them to be associated with the lemniscal and the spinal thalamic components of the somatic afferent system, respectively The combined electrophysiological and behavioral studies of somaesthetic sensitivity in animals provide the basis of our current understanding of the system (Mountcastle et al , 1966)

Temperature Sense

Temperature is an index of relative heat Temperature, as such, is therefore probably not appropriately considered a physical stimulus, but it is a most satisfactory index of the possible effects of increases or decreases in the amount of heat in living tissue The temperature of various parts of the body may vary over a relatively narrow range without danger, but excessive heating or cooling can cause damage Temperatures above 45° C may result in protein denaturation (Hardy et al , 1952) This is associated with the sensation of pain Very low temperatures may also cause tissue damage but the anaesthetic effect of cooling under the appropriate conditions may conceal the fact that damage is being incurred and pain is not sensed until the cool tissue is reheated

Well within the range of noninjurious amounts of heat, receptors respond to relatively small amounts of temperature change The resulting sensations are of warmth or coolness These sensations are not painful and are qualitatively quite different from the sense of touch It is, therefore, reasonable to assume that they may be mediated by specialized receptor endings The receptor system for the detection of thermal variations provides a basis for the voluntary regulation of activity and the amount of clothing worn The system is also involved in reflex mechanisms which permit the close regulation of body temperature

RECEPTORS FOR THERMAL SENSITIVITY

Two types of end organs are characteristically associated with thermal sensation These are the Krause end organs (Fig 8 133*B*) associated with the discrimination of cooling, and the Ruffini end organs (Fig 8 133*C*) associated with the sensation of warming The Ruffini end organs may also be stimulated either electrically or mechanically and, if the stimulation is controlled appropriately, it will produce a sensation of warmth A Ruffini end organ is frequently found located near a deep plexus of blood vessels

METHODS OF STUDYING THERMAL SENSITIVITY

One of the earliest techniques for studying responsiveness to temperature change involved the use of thermal probes, often metallic containers with a blunt tip, the temperature of which could be controlled by the use of a hot or cold liquid contained in the device Investigation of the surface of the skin of human subjects has revealed regions with increased sensitivity to cold or warmth similar to those referred to above for touch Considerations of responsiveness to a variety of stimulus dimensions reveals that there are relatively fewer selectively responding spots for the detection of cold and tactile stimulation, as compared with warm and painful stimulation This may have evolved as a result of the fact that warm stimulation more frequently presages possible injury than does cold, and it is obvious that painful stimulation is typically an indication of potential injury

The thermal sensory system may be studied in terms of regulatory reflexes or the behavioral responses of animals Such types of investigations may be associated Reflex thermal regulation is treated in detail elsewhere

A third method of studying the temperature sense involves electrophysiological recording from single neural units in animal preparations or even in human subjects Some fairly recent data have been obtained with these techniques which help to verify the nature of the temperature-sensing system

Hensel (1966) and his colleagues have examined quantitatively the nature of the response of single fibers in a variety of organisms with changes in the temperature of stimulation of

an appropriate region of the surface of the skin The results make it clear that certain fibers are associated with cold receptors and others with warm receptors The discharge frequency in the cold response system is increased by any relatively abrupt decrease in temperature When there is no resting level of discharge, warming has no effect on these units A resting level of discharge may be inhibited by the presentation of a warm stimulus Stimulation of the region of the skin which produces a response to temperature change by a mechanical probe ordinarily produces no response or shows a very high threshold for mechanical stimulation The responses of a single cold fiber in the radial nerve of man are illustrated in Figure 8 136 It is evident that as the continuous trace which represents changing temperature drops, the discharge frequency of the fiber increases With subsequent increase in temperature the discharge frequency is again reduced Increased discharge frequency may be initiated for drops from a variety of initial temperatures, but the maximum rate is achieved for reductions in temperature from the region of 20° C

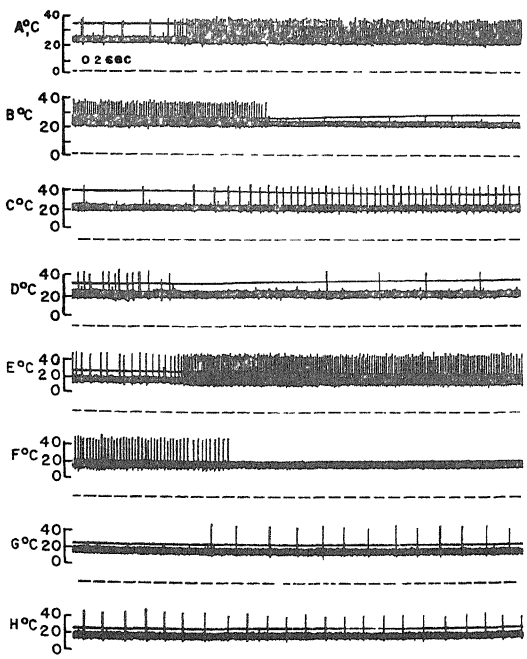

Fig 8 136 Afferent impulses in a single cold fiber in the radial nerve in man and temperature during cutaneous thermal stimulation (A) Start of cooling from 34° to 26° C (B) start of rewarming (C) start of cooling from 38° to 35° C (D) start of rewarming (E) start of cooling from 24° to 16° C (F) start of rewarming (G) 13 sec after rewarming has started (H) continued from record (G) (Hensel 1966)

Warm receptor systems are identical except that they respond in the opposite way to changes in temperature, rapid warming causes an increase in discharge frequency, while cooling either has no effect or inhibits a resting discharge frequency

Changes in response have been noted in a variety of animals (including the monkey) for a change in temperature as small as 0 2° from an initial value of 33° This compares reasonably well with the threshold change in temperature required for the elicitation of a warm or cold response in man

Both cold and warm receptor systems show a change in resting discharge frequency with a change in the sustained temperature level The resting discharge is a maximum for the warm system for temperatures between 38° and 43°, for the cold system between 15° and 34° The maximum discharge frequency ranges from 2 to 15 impulses/sec The characteristic response of a cold or a warm receptor system is seen only for relatively abrupt changes in temperature If the change is gradual, both the warm and the cold systems will show an increase in discharge frequency with increased temperature from below the range of maximum response up to that range, and a decrease in discharge frequency for increases in temperature above the optimum range

Stimulation of the Krause end organs by increase in temperature up to the vicinity of 45° C has been shown to be associated with the sensation of cold The electrophysiological correlate of this has been reported by Zotterman (1953) in cold fibers of the cat which are again activated with increase in temperature up to 45° C, and which continue to respond up to a maximum temperature of approximately 50° C The sensation of "paradoxical cold" can be observed in human subjects if the region of stimulation of the skin is selected carefully, and a stimulus temperature of approximately 45° or a little higher is employed

Certain sensory fibers have been found which show a change in discharge frequency for both mechanical stimulation and to reduction in temperature These are much less sen-

sitive to changes in temperature than the receptor systems we have been discussing, however Where the change in discharge frequency in impulses per second for every degree centigrade change in temperature may be of the order of 30 to 55 for units which respond only to thermal stimulation, this same index of response reduces to the order of 1 to 5 impulses/sec for each degree centrigrade change in temperature in those units which respond both to pressure and to cooling In human subjects, the stimulation of such receptors by mechanical means never produces a sensation of cold, but the application of a thermal stimulus may be perceived as a change in pressure It, therefore, seems reasonable to assume that these systems are in fact pressure-sensing systems

THEORETICAL CONSIDERATIONS

One hypothesis that has been suggested is the idea that the appropriate stimulus for a thermal receptor may be a gradient of temperature across its physical extent Thus, if the outer portion of the peripheral receptor is cooler or hotter than an inner portion, the result is a change in the discharge frequency of the system The possibility that this may be so has been refuted by showing that the introduction of a thermal stimulus, either above or below the receptor, has the same result in terms of change in discharge frequency It is, therefore, fairly clearly established that the appropriate stimulus is a change in temperature of the whole receptor termination

The question has been raised as to whether the specialized receptors in the skin for touch, temperature, and pain may all be basically chemoreceptors which respond to a transmitter substance which may be released by ancillary cells when an appropriate stimulus is applied (Mountcastle, 1966) The idea is an interesting one but it does not seem necessary for certain receptor types such as the Pacinian corpuscles (Loewenstein, 1966)

From our discussion of the warm and cold receptor systems studied by Hensel, it would seem that the coding of these dimensions of thermal response is accomplished by the specific responding neurons Some of the behavioral work of Kenshalo (1968) has been interpreted to suggest that coding may be in the form of increased activity for cold and decreased activity for warmth, but direct recording from single fibers does not accord with this opinion

Pain

Pain is an extremely important sensation by reason of the role it plays in the protection of the organism from hazardous agencies in the environment Reflex withdrawals mediated by a painful stimulus prevent or minimize burns, cuts, and all manner of potential injuries In addition to its direct relation to protective reflexes, pain is important for the learning of an organism to avoid future contacts with painful agents once encountered In our civilized society the survival value of pain is based on still an additional dimension of usefulness For the physician, the patient's report of pain, its location, its quality, its intensity, and its duration may play an extremely important role in medical diagnosis The clinical study of the significance of pain in injury and disease represents an extensive field which cannot be treated in detail here, however

STIMULI AND RECEPTORS

It has been extremely difficult to identify specific receptors which mediate pain There are very few tissues of the body which will not respond to damaging stimulation with pain Studies of single fibers render it clear that there are specific pathways which mediate pain sensations, but the receptors with which they are associated have not been clearly identified It is probable that a variety of cutaneous receptors and receptors for sensations other than pain within deeper tissue may provoke a painful response when the stimulus is extreme The best subjects for the study of pain are human subjects, by reason of their ability to provide a verbal confirmatory report of painful or uncomfortable sensations in response to stimulation Pain must be inferred in animals from observation of the behavioral correlates of the sensation in humans

Another problem arises from the fact that painful stimuli, except when very near threshold levels, usually are damaging to tissue Tissue which is damaged cannot be expected to continue to respond in the normal way Thus, in attempting to study pain in an animal preparation, the investigator may be altering the system in some fashion which will influence his results and his conclusions If he attempts to restrict stimulus intensity to a near threshold level, it may be virtually impos-

sible to determine that the effect of stimulation is indeed painful

The "pain" system is probably involved in nonpainful as well as painful sensations It has been associated with the sensation of taste of certain spicy foods (Lee, 1954), and as will be discussed below, may be associated with "tingling" or "itching" sensations which are not always unpleasant This additional role of the pain receptors and the neural pathways which mediate their response renders the study of the system in lower animals even more difficult

Pain Localization The localization of a painful stimulus is obviously of some importance if the sensation is to provide a basis for escape or withdrawal from the stimulus Localization of pain is reasonably good, but it does not have to be completely precise When the pain originates on the external body surface or in a limb, the withdrawal reflexes involve relatively gross movements of the whole body away from the source of stimulation, or flexion withdrawal of an entire limb There are certain circumstances where the localization of the pain as contrasted with the site of injury may be grossly in error For example, when there is injury to a nerve pathway which mediates pain sensation, the sensation may be projected to the origin of the pathway, such as a limb, although the actual injury may be in the region of the spinal cord The fact that a painful sensation may be projected to a region which has suffered no damage may in no way mitigate the extent of the pain, however

Another error in localization occurs with what is known as *referred pain* Damage or injury in a certain region may result in a painful sensation associated with a region somewhat removed from the locus of the injury This phenomenon differs from the projection of pain in that the region to which the pain is referred is not a more peripheral location along a nerve pathway passing through the locus of injury The pain associated with visceral injury or pathology is quite frequently referred to regions of the trunk somewhat removed from the focus of actual irritation The way in which erroneous localizations are associated with irritation in the gastrointestinal tract follows a fairly characteristic pattern, however, and the region where the pain is sensed may provide important information for diagnosis of the actual site of irritation

The Receptors for Pain. As indicated above, it has not been possible to make clear-cut identifications of pain receptors which uniquely serve the mediation of a pain response They probably are unspecialized endings in the skin and in other regions, and their existence is strongly supported by the existence of small diameter myelinated and unmyelinated fibers of slow conduction velocity which have been fairly clearly established to serve the sensation of pain (Clark et al , 1935) The regions of the body in which pain is experienced make it clear that these receptors must exist in skin, muscle, the viscera, the cornea, arteries but not veins, periosteum, and cancellous bone

Pain Stimulation Pain endings apparently respond indiscriminately to any stimulus, mechanical, chemical, or thermal when it is sufficiently intense The one generalization which can be made is that a painful stimulus, by reason of its nature or its intensity, is capable of causing injury An exception may be the stimuli which excite deep pain endings These may be located in muscles, tendons and joints, or in the periosteum Mechanical stimulation which would not cause pain in normal tissue may provoke a response following injury or infection Apparently, the deep pain endings greatly increase in sensitivity to mechanical and chemical stimulation as a sequel to injury or infection Muscle pain may result from prolonged muscular contraction Muscles become much more sensitive to pain during prolonged or even intermittent contraction when their supply of blood is reduced or interrupted This has been associated with the release of a chemical which is a product of muscle metabolism Its identity is unknown Pain does not occur with intermittent contraction of normal muscle, and it is relieved fairly rapidly in ischemic muscle when circulation is restored Even after the muscle contraction has ceased, the pain may continue in muscle which is deprived of blood until the normal supply is restored

For the scientific study of pain, it is desirable to employ quantitative methods of stimulus specification One procedure which has been widely used in stimulation of the skin involves controlled heating (Hardy et al , 1952) A region of the skin is blackened with India ink in order to equalize the absorptance of the skin of individuals with varying pigmentation A known amount of radiant heat from a calibrated lamp may then be applied in a restricted area for various durations Heating of the tissue may be measured fairly accurately

Pain is associated with the elevation of skin temperature to the neighborhood of 45° C, and a qualitative scale of increasing pain intensity may be related to increasing amounts of thermal stimulation Another method developed more recently for the study of chemical agents which may stimulate pain consists of the production of a blister base on the skin such that chemicals may be directly applied after the epidermis has been removed and any painful response associated with the creation of the blister has subsided (Keele, 1966) One problem with the use of some chemical agents is their indiscriminate excitation of a variety of receptors, in addition to those which may be uniquely associated with the pain response The blister base technique has proven useful for the comparative evaluation of a number of agents which may evoke a painful response in humans, nonetheless

PAIN AS A SENSATION

The Response to Pain The threshold for perception of pain based on quantitative studies with thermal stimulation has proven to be remarkably stable among individuals The perception threshold can be influenced by distracting agencies of a wide variety, e g , by hypnosis, by alcohol, and by certain drugs Ordinarily, however, the same amount of stimulation will result in a threshold perception in the same individual from one time to another, as well as in different individuals The nature of the reaction to painful stimulation, on the other hand, varies greatly from subject to subject It also varies greatly in a given subject depending on circumstances On a battlefield, serious injuries may be ignored and appear to cause the injured person remarkably little inconvenience Under other circumstances the same individual might be completely incapacitated by a lesser injury There is some question as to whether the effect is on the sensation of pain itself or on the nature of the reaction to that sensation (Melzack and Casey, 1968) Patients who have been given morphine, or others with frontal lobe lesions (Freeman and Watts, 1948) may be able to report pain sensation at the same stimulus level associated with the perceptual threshold in normal subjects, but the painful sensation no longer elicits the typical normal reactions It is as if the pain sensation alone "doesn't hurt!" Melzack and Casey have argued convincingly for a broader interpretation of "pain" than that possible when it is viewed as purely sensory It is certainly well established that the affective concomitants may be much more important in the determination of reaction to pain, and these affective concomitants are not always well correlated with the level of stimulation and, presumably, with the intensity of sensation

The Quality of Pain. Any one who has lived long enough to read this account is well aware of the great variety of painful sensations A pain may be characterized as "sharp" or "dull " It may be throbbing or sustained Sharp, bright, or pricking pain is usually of short duration A burning pain is more prolonged The "burning" quality of pain is not necessarily associated with a thermal stimulation Deep pain, originating in the tendons and joints or in the viscera may be associated with a drop in blood pressure, a slowing of the pulse, sweating, and nausea Such pain is often characterized as "sickening" and may even be accompanied by vomiting Cutaneous pain is more often associated with an increase in pulse rate and elevated blood pressure

Hyperalgesia The qualitative nature of a painful sensation may be altered following injury In an extended region around an injury to the skin, the threshold for sensation of pain may be slightly lowered and pain, once aroused, may be diffuse and extremely unpleasant (Lewis and Hess, 1933) The threshold may be changed relatively little or not at all, but stimuli which would normally create only mild irritation elicit a relatively intense and sustained pain response Similar effects in the skin may result from an injury to deeper tissue or underlying mucous membranes The extended region in which response to painful stimuli is changed is referred to as an area of *primary hyperalgesia* There is erythema or reddening of the skin as a result of vasodilatation The effect is not immediate upon injury, but may follow an interval during which there is little or no pain This suggests that the hyperalgesia does not result from continuing hyperactivity of damaged cells Rather, it is attributed to a release of some chemical substance in the injured region by the damaged tissue and in surrounding regions as a result of action of the nerve fibers which are involved

Another kind of hyperalgesia, *secondary hyperalgesia*, may be elicited by repeated electrical stimulation of a focal region of the skin

A change in response to painful stimulation occurs in a region around the point of stimulation this kind of hyperalgesia extends well beyond the region of erythema There is no reduction in threshold and, in fact, threshold may actually be increased slightly The sensation of pain, once aroused, is much more intense than normal The duration of secondary hyperalgesia is typically much shorter than that of primary hyperalgesia The latter may last for many days following severe injury

THE NEURAL PATHWAYS FOR PAIN

The early work of Clark et al (1935), showed that the high threshold afferent units associated with pain sensation are to be found among small myelinated and nonmyelinated fibers, slowly conducting C-fibers The work of Brown and Iggo (1967) has established that the majority of small myelinated fibers are excited by stimuli which can hardly be considered noxious The problem remains of determining which fibers are specifically associated with the conduction of pain information Some method must be conceived of selectively stimulating pain endings in the skin of experimental animals Perhaps the only solution, as suggested by Iggo, is a systematic effort to catalog the stimulus situations which give rise to pain in man and then identify those fibers and hopefully, receptors, which only respond to such stimuli when they are applied to animals It is clear that all small, nonmyelinated fibers are not exclusively pain pathways in the skin, muscle, or viscera The problem of selective study of pain pathways arises from the fact that a diversity of pathways in addition to those which are exclusively assigned to pain are brought into play by any stimulus which will elicit a pain response Even certain pathways which respond only to relatively high levels of stimulation may not mediate pain (Iggo, 1957, Titchen, 1958)

Combined Sensations

Tickling and itching have been associated with the stimulation of both touch and pain receptors A tickling sensation may not be detectable after injury to the lateral spinal thalamic tract, although stimuli can elicit sensations of touch On the other hand, when the sensation of touch is reduced or lost during moderate ischemia there is also no tickling sensation In this case, the sensitivity to pain remains If the lateral spinal thalamic tract is primarily concerned with pain response, then it would appear that tickling requires function of both the touch and pain receptor systems

Itching may be determined exclusively by the pain system (Rothman, 1943) or may, in some circumstances, depend upon both the touch and pain systems Spontaneous itching may depend upon the pain system exclusively It is unalleviated by relative ischemia which reduces or eliminates touch sensation Itching is believed to result from stimulation by a chemical mediator which is released when cells are damaged It may also be elicited by mechanical or electrical stimulation (Arthur and Shelley, 1959) Any agent which eliminates pain will also eliminate itching

The difficulty in identifying specific receptors for various cutaneous sensations and the evidence that nonspecified endings may subserve a variety of sensations have sometimes raised the question of whether the various skin sensations are properly considered independently The differential response of these various sensations would suggest that they do represent independent systems For example, touch is eliminated first by ischemia or reduced blood flow On the other hand, with the administration of cocaine, the sensation of cold, warmth, pain, and touch are lost in that order Local cooling of the skin results in loss initially of the sensation of cold, followed by touch, pain, and finally warmth

Neural Control Systems

1 / ANALYSIS OF NEURAL CONTROL SYSTEMS

Classes of Neural Components

Every neural control system is made up of relatively few types of cells The control is always exerted finally upon a muscle (either striated, cardiac, or smooth in its histology) or upon a gland (either exocrine or endocrine) Thus, there are only two general types of *effector cells*, muscle and gland For these two kinds of cells, however, there are three types of control (Fig 9 1) One type is peculiar to skeletal muscle, another is common to cardiac muscle, smooth muscle, exocrine glands, and a certain few of the endocrine glands, the third is reserved for endocrine glands only In each instance the operation of the control system brings about the shortening or lengthening of the muscle, or the secretion or cessation of secretion of a gland

EFFECTORS AND DETECTORS

Nerves that control muscles and glands are known as *effector nerves* Most of them leave the central nervous system via the ventral roots of the spinal cord or the equivalent roots of cranial nerves Consequently, they are known as *efferent* because their course is away from the brain or spinal cord They are also known as motor nerves, although this term is hardly appropriate for those that control glands

In contrast to the effector cells are those specialized cells that respond to local or environmental changes by sending signals into the nervous system These cells are known as receptors, as *detectors*, or as "sensory" cells if this last term is understood not to imply conscious sensation Their nerves are called *afferent* because they run toward spinal cord and brainstem, they are also called "sensory" merely because there is no other convenient word that is more precise in its meaning Whereas the cell bodies of effector nerves are located in the central nervous system or in ganglia of the autonomic nervous system (pp 9-53–9-65), the cell bodies of detector nerves ordinarily lie in ganglia on the dorsal roots of spinal nerves or within the homologous ganglia of the cranial nerves

In general, the principles of organization of detector-effector systems are similar in spinal and in cranial nerves, with two exceptions These two are the first two of the cranial nerves, the olfactory and optic Fibers in these nerves are not processes arising from detector mechanisms Rather, they are the analogues of fiber tracts within the central nervous system This comes about because the olfactory bulb and the retina are derived from the embryonic brain and not from the neural crest, as are the other peripheral and cranial sensory nerves In fact, the fibers of the olfactory and optic "nerves" are longitudinally coursing commissures of the brain

There are a very few types of neural control where the system includes only the detector cell and the detector nerve, and then a direct connection with the effector nerve and thence with the effector cell Such a system is known as a *two-neuron arc* or *monosynaptic reflex* Under laboratory conditions this type of reflex can be demonstrated by stimulation of a dorsal root so as to evoke a reflex discharge in the ventral root Such reflexes are transmitted through the spinal cord with a shorter delay than other types of transmission, and have been employed as measures of the time required for the afferent neuron to excite the efferent neuron of the reflex The site of this excitation is the *synapse*, a region of intimate contact but not fusion of the two neurons Delay in transmission across a single synapse is in the neighborhood of 0 6 msec (Renshaw, 1940) What happens in this interval is de-

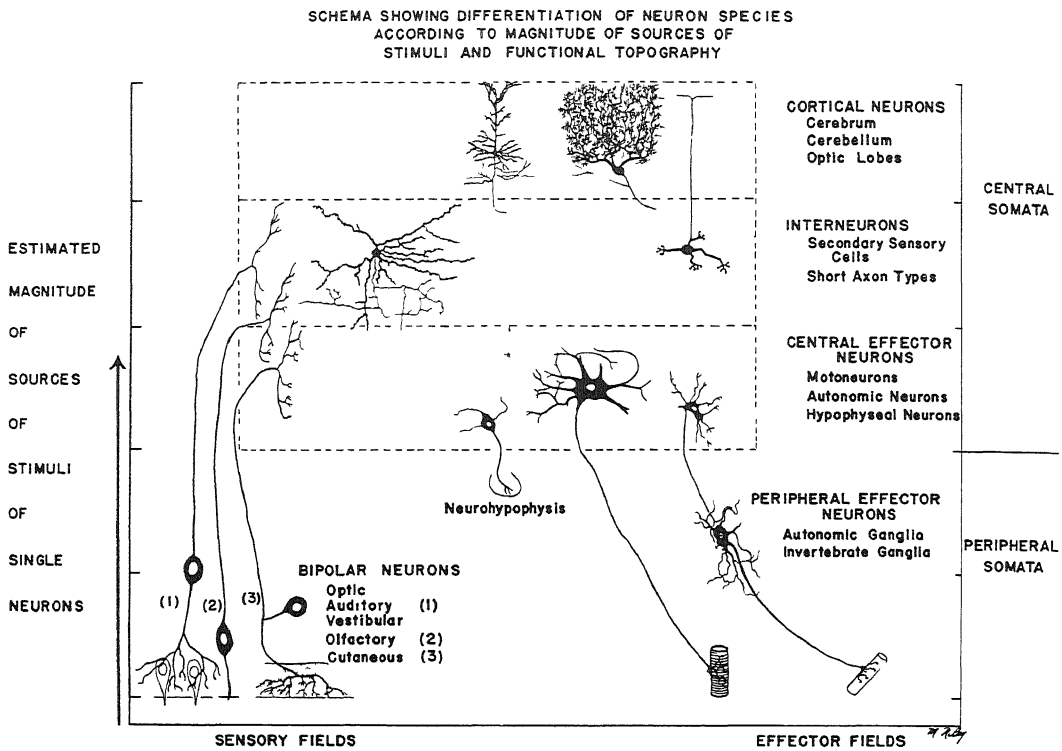

Fig 9 1 Major neuron types in mammalian central nervous system classified according to general function hierarchical level and probable diversity and magnitude of sources of synaptic connections Bodian in Quarton et al 1967

scribed in section 1 of this text, and reconsidered briefly on pp 9-76–9-82 The experimental situation where these measurements are made, however, is scarcely a physiological one, and it seems doubtful that there is any naturally occurring control process where only two neurons can be said to participate in the response One can speak, therefore, of a two-neuron reflex, but probably there is no two-neuron control system for skeletal muscle

CONNECTORS

If two-neuron arcs are not common, then most responses must involve units other than the detector-effector combination These other units are called *connectors*, or internuncial cells or interneurons Their morphology is essentially the same as that of detectors and effectors, in that they receive, propagate, and transmit a disturbance, i e , a *nerve impulse* By their presence in a neural pathway they increase the delay of transmission because of the introduction of their additional synapses Their significance, however, far exceeds this perhaps trivial phenomenon, because they have the highly important property of being able to reverse the "sign" of neural activity If the customary effect of a detector neuron upon an effector neuron is excitation, the interposition of a connector neuron may convert the process into its opposite, namely, a suppression of activity This suppression is known as *inhibition* It is inhibition in the neural control system that permits one muscle to relax when its opposing muscle contracts, and that makes possible the almost infinite gradation of the force of any movement

Another function of connector neurons is the introduction of complexity into control systems (Fig 9 2) A network of nerve fibers linking detectors with effectors via multiple alternate pathways that include connectors has the possibility of actions more complex and also more subtle than any two-neuron system In this sense the connector neurons are analogous to the plug-in cords of a telephone manual switchboard It is true that every telephone could have a direct line to every other telephone in the system But it is apparent that the bulk of wiring to every telephone

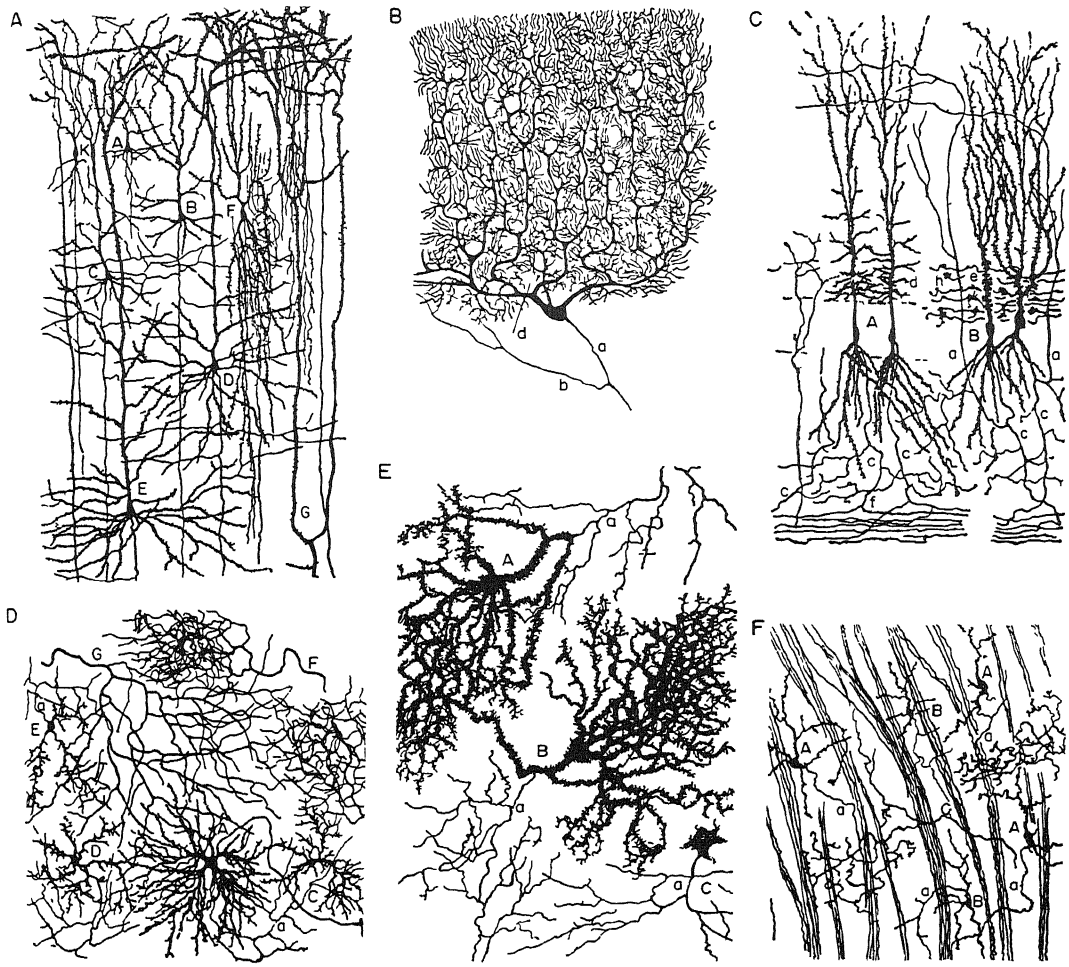

Fig 9 2 Examples of dendritic patterns of neurons which constitute the major cell types of elements in different structures of the mammalian brain *A* outermost three layers of frontal cortex of a 1-month-old human infant Small (*A B C*) and large (*D* and *E*) medium pyramidal neurons as well as the dentritic process of a large pyramidal cell (*G*) of the fourth layer are shown Cells with double dendritic bouquets (*F*) and fusiform appearance (*K*) are also identified *B* Purkinje cell of the cerebellum from adult human Axon (*a*) and axon-collateral (*b*) capillary spaces (*c*) and spaces occupied by basket cells (*d*) are indicated *C,* Pyramidal cells of hippocampus from a 1-month-old rabbit *A* small pyramidal cells of the superior region *B* large pyramidal cells of the inferior region Large ascending collaterals (*a*) axons (*c*) and sites of contact of mossy fibers (*h*) are to be noted *D* Frontal section of the thalamic somatic sensory nucleus of the cat a few days old *A* cell with a long axon *C D* and *E* cells with short axons *F* sensory fibers *G* axons of cortical origin terminating in the sensory nucleus *E* Cells of the pons from a human infant few days old *A* and *B* cells with axons arising from dendrites *C* cell with a bifurcated axon *F* Sagittal section of the caudate nucleus from a newborn rat *A* cells with a long axon *B,* cells with short axon *C* ascending afferent fibers From Ramon ŷ Cajal cited by Purpura 1967

would thereby become enormous By making these interconnections at a central station an economy of number and bulk of peripheral transmission lines is achieved, and the possibility of interconnections is multiplied One sees from this analogy that peripheral nerves can be fine because they only transmit nerve impulses, whereas the spinal cord, brainstem, cerebellum, and cerebral cortex must be relatively more bulky if they are to contain the central stations for the switching processes The size of a given part of the nervous system is largely a function of the number of neurons it contains, and hence is an index of the variety and complexity of its function

In their ability to alter the nature of activity

in a neural circuit, either to increase it—*facilitation*—or to inhibit it, and in bringing into any circuit the possibility of a wealth of alternate connections, the interneurons give the nervous system an enhanced capacity for what Sherrington (1906) called an *integrative action* By this term he meant the creation of an individual from its component reactions Relaxation of an extensor muscle during contraction of a flexor is an integrative action, as is the contraction of extensors in the left leg when the right leg is flexed A certain degree of integration is programmed into even the simplest reflexes in that the detectors make connection with appropriate effectors, rather than with effectors remote and unrelated to the initial stimulus Yet in most instances and especially in higher components of the system the integration depends largely upon interneurons The nature of the individual assembled from unitary responses is a function, therefore, of the number of connector units, the diversity of their connections, and the complexity and variety of controls their activity brings into play [1]

Methods of Physiological Study

ANALYSIS OF NEUROLOGICAL DEFICITS

A "natural" method for studying control systems is provided by disease and trauma affecting the nervous system of human patients, and domestic or other animals Analysis of deficits under such circumstances is the oldest method of study, and the one upon which a large fraction of all that is known about the human brain depends Injuries, known as *lesions*, occur as a result of nutritional deprivation, poisoning, infection, tumors, vascular occlusion, hemorrhage, and both indirect and direct mechanical trauma Because certain parts of the nervous system are relatively small, even a tiny lesion may result rather promptly in a considerable variety of deficits The patient may complain of *symptoms* produced by the lesion, while his physician discovers objective *signs* of abnormal function. It is the spinal cord and brainstem where small injuries may lead to pronounced changes In the cerebral cortex by contrast, where functions are more subtle and the systems seem to possess a high degree of "redundancy," even relatively large lesions may go unrecognized The objectives of a neurological examination are to identify the site of the lesion, to delimit its size, to discover whether it is increasing in size or severity, and if so, how quickly, and to decide if possible what has caused the injury Making these decisions not only requires careful and detailed examination, it also requires a comprehensive knowledge of the location of mechanisms within the neuroaxis In many instances the knowledge that is most useful is the distribution of spinal nerves, and the location of cranial nerve nuclei in the brainstem The former can be ascertained easily from published maps The latter, however, is of importance so great as to be deserving of being memorized by every physician Because the cranial nerve nuclei extend through the brainstem from upper mesencephalon to lower medulla oblongata, when they are included in a lesion the resulting signs or symptoms may give invaluable information about where the lesion is and how extensive it may be

Neurological examination utilizes an ancient method of study in which a patient is either asked to perform some act, is requested to describe some experience, or is stimulated so as to provoke a sensation or a motor response In each of these procedures an *input* to the nervous system is created either verbally or by stimulation, and an *output* is always hoped for either in speech or other motor response In a qualitative sense these techniques analyze the input-output relation of the part of the nervous system being investigated Methods that are in their logic exactly the same are utilized by engineers in analysis of electrical and electronic instruments—or by a mechanic working on a motor car, for that matter Opening the throttle to discover what noise the motor makes is an example of input-output analysis of a crude variety If it is possible to quantitate the stimulus applied, for example, to the skin or to one of the organs of special sensation, and if it is possible to measure the strength of the response, then the techniques of neurophysiology come even closer to those utilized for study of inanimate systems One of the most striking examples of such an experiment

[1] Electrical and mathematical models of how neurons interact may be found in papers by Harmon and Lewis (1966), Kennedy, et al (1969), and George (1970).

Table 9 1
Strength of contraction of *M Tibialis Anticus* (flexor of the foot) in response to stimulation of various cutaneous sensory nerves Upon direct stimulation of the motor nerve the maximal force of contraction of the muscle was 2160 gm

Afferent Nerve Stimulated	Tension of Maximal Reflex Tetanus in Grams	Reflex Tension Expressed as Percentage of Maximal Motor Tetanus
Internal saphenous	800	32
Superficial obturator	165	6 7
Deep obturator	400	16
Nerve to quadriceps and sartorius	1190	44
Musculocutaneous branch of peroneal	1700	69
External plantar	1240	50
Internal plantar	1330	54
Small sciatic	680	28
Hamstring	565	23
Nerve of sural triceps	300 (rather low)	12
Total	8370	

Creed et al , 1932

is found in a table published by Sherrington and his associates (Creed, et al , 1932) and reproduced as Table 9 1, it compares the strength of muscle contraction after stimulation of various cutaneous, sensory nerves Sherrington was able to predict the nature of the connections between afferent and efferent neurons in the spinal cord on the basis of the data in this table In these experiments the input was strong electrical stimulation of the sensory nerves one after the other, the output was the strength of the resulting contraction of the tibialis anticus muscle

Deficits following Experimental Operations. During the development of the specialty of neurosurgery in the early years of this century, surgeons began to operate upon experimental animals for the purpose of learning more about functions of the brain, so that neurological diagnosis and surgical intervention might be more effective At first the experimental lesions were made by ablation, or by incision, and they involved principally the hemispheres of cerebrum or cerebellum because they are accessible to such operations The deficits that follow such an ablation may yield important information about the nature of a control system if some component of the system is well localized in a given part of the brain This is true of the principal motor and sensory systems that are represented just ahead of and just behind the central sulcus on the lateral convexity of the cerebrum But if a given system is diffusely organized, as seems to be the case for other cortical mechanisms, or if a given part of the brain includes components belonging to many different systems, the technique of ablation may have limited usefulness, and may actually yield confusing results The neurosurgical approach is handicapped also by the obvious difficulty of removing an underlying structure, such as one of the basal ganglia, without injury to the overlying tissue

Stereotaxic Surgery. To obviate some of these limitations, and especially to make possible the study of subcortical structures, an English physician-physiologist, Robert Henry Clarke, and his better known neurosurgical colleague, Sir Victor Horsley, invented a technique known as stereotaxic surgery (see Davis, 1964) For this invention Clarke has been called "the Galileo of neurophysiology" (Tepperman, 1970) His method employs a calibrated frame fastened to the head of the subject On the frame is a carrier that can be moved from side to side, from front to back, or up and down, it carries one or more instruments that can be thereby oriented at predetermined positions within the brain If the instrument inserted is an insulated wire, it may be used for stimulation, for destruction of tissue by electrolysis, or for recording (Fig 9 3) Lesions made by electrolysis using direct current may be as small as a millimeter in diameter, or up

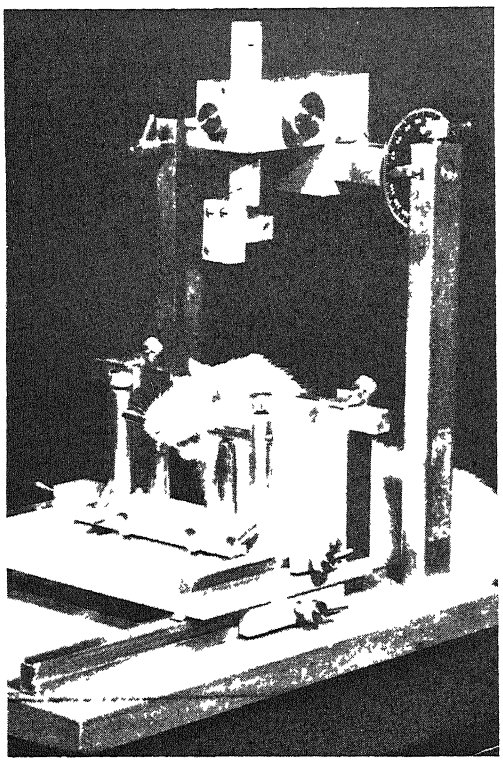

Fig 9 3 Stereotaxic instrument (Baltimore) for use on cat rat or mouse The head holder moves rostrocaudally the electrode carrier moves from side to side and up and down and rotates around the top pivots

to a centimeter if the electrolysis is repeated at many positions (Carpenter and Whittier, 1952) The method may be used also for injection of material through a needle or hollow tube, or for incision of tissue by means of knifelike wires designed for this purpose Stereotaxic instruments are available commercially for animals as small as mice, as well as for operations upon human patients (Fig 9 4). They may be used for *implanting* electrodes or tubes, in an operation performed under anesthesia where the implanted instrument is fixed to the skull so that it may be utilized long after the subject has recovered from the effects of the operation (see Anon , 1971) All of these advantages combine to give stereotaxic operations a pre-eminent place in the techniques of neurophysiology

Recovery from Operations. One of the interesting characteristics of lesions made experimentally, which has a parallel in the experience of many patients with vascular lesions of the cerebrum, is the discrepancy between the initial and the ultimate deficit (Stein et al , 1969) For example, operations upon the rostral hypothalamus of cats may be followed by a fever during which the animal dies, although if the cat is cooled artificially during this period and kept alive until the fever disappears it will attain a fairly normal temperature (Clark et al , 1939) The observation that recovery occurs in patients who have a paralysis, or a sensory disturbance, or a speech defect as a result of occlusion of a cerebral blood vessel is a common clinical experience In many cases the recovery is regarded as "complete," even though neurons of the central nervous system are known to have practically no capacity for regeneration of severed processes Moreover, in mammals, after birth neurons can no longer be produced by multiplication or differentiation of primordial cells How then can recovery be explained?

The first and most obvious possibility is that neurons made inactive by the injury may later recover their function This type of recovery is known to occur after pressure is applied to a nerve, after cooling, anoxia, or the action of local anesthetics Very probably such a se-

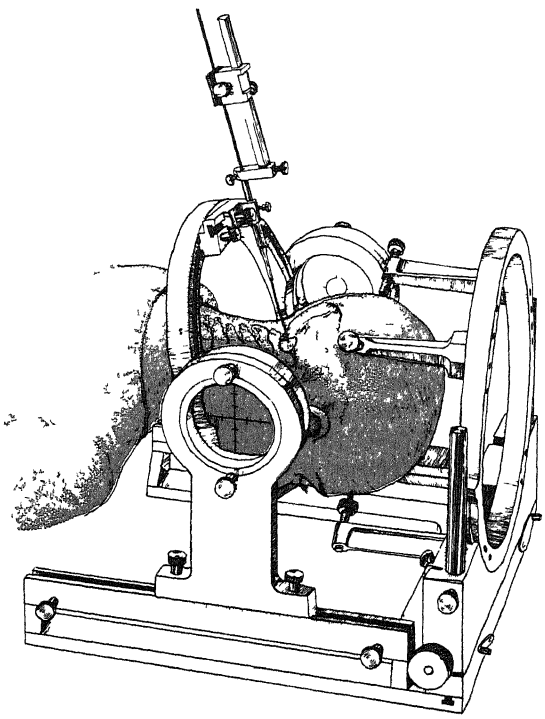

Fig 9 4 Stereotaxic operation upon a human subject The instrument is in place for insertion into the cervical spinal cord Courtesy of Dr E M Todd San Marino California

quence of events takes place at the margins of a lesion following vascular occlusion or electrolysis It may be that the number of temporarily inactivated neurons far exceeds those cells that are in fact "destroyed," with the result that recovery does indeed depend upon restoration of function in many neurons Another possibility is that the lesion has not fatally damaged the whole system, but has removed one component such that remaining parts are temporarily out of balance An automobile may go too fast when the brakes fail suddenly, but it is possible to drive a car at conventional speeds even if it has no brakes With reference to the fever after injury to the rostral hypothalamus, the hyperthermia may be a result of release of the system from a usual hypothalamic inhibition But the fever may disappear when other parts of the system once again achieve a more harmonious balance, even though a component no longer functions Another example may be the phenomenon of recovery from spinal "shock" After transection of the spinal cord there is depression or absence of spinal reflexes below the section, in most laboratory animals these reflexes gradually return, the duration of the recovery ranging from minutes or days in rats, to days and weeks in cats The conventional explanation is that removal of facilitatory influences from higher mechanisms left the spinal neurons at first relatively unexcitable, but that they later recovered the ability to respond to reflex type of stimulation even in the absence of descending facilitation

A third possible explanation is that other neurons have taken over the function of those that were destroyed This possibility is uncertain and controversial (Lashley, 1929), and perhaps related to the phenomenon called "learning" In the spinal cord and brainstem it seems highly questionable whether such a transfer of function can occur, because even tiny but well-placed lesions may cause permanent deficits Finally, there is the possibility that the function being analyzed may be effected through redundant systems, and that the lesion has removed only a part of the participating mechanisms What is called recovery may be simply the action of the "back-up" systems' taking over the function If this is true, it should be possible by suitable testing to demonstrate that a deficit remains in spite of the recovery This can be done in animals that have survived the postoperative fever of rostral hypothalamic injury After they have regained a normal body temperature under laboratory conditions, they experience another bout of fever if they are exposed to a warm environment This observation demonstrates another important point, moreover, that a test is useful only if it succeeds in revealing a specific deficit The input of the test must be selected so that it will disclose whether or not some defect in output is present

Analysis of Subtle Deficiencies. One sees, therefore, that the value of any study of a patient or a laboratory animal depends upon the ingenuity and care with which any deficit is displayed and analyzed In clinical neurology one of the most significant of the tests available is simply careful observation of a patient's posture and locomotion More than a casual approach is needed, however, along with a thorough knowledge of the location of both sensory and motor mechanisms in cerebrum, cerebellum, brainstem, and spinal cord One is inclined to emphasize the value of a systematic neurological examination because so many students suppose that only a neurologist can perform one adequately On the contrary, the fundamentals of a neurological examination should be within the skill of every physician

In the design of neurological tests the discipline of experimental psychology has had an important influence The use of conditioning techniques, those requiring solution of problems such as maze running, the ability to discriminate between minimal differences in sensory cues, and many others have greatly extended the scope of study of neurological deficits (chap 8) It is in this direction that further progress in understanding of the nervous system is likely to take place, as new and imaginative techniques are devised for disclosure of hitherto unknown input-output relationships

ARTIFICIAL STIMULATION

A second type of study of the nervous system, either intact or following some operation or injury, depends upon the use of a specific, controlled stimulus, of measured intensity if possible Tapping a tendon to produce a muscle twitch, or stroking the sole of the foot to evoke movement of the great toe are familiar examples Electrical stimuli may be applied directly to peripheral nerves, espe-

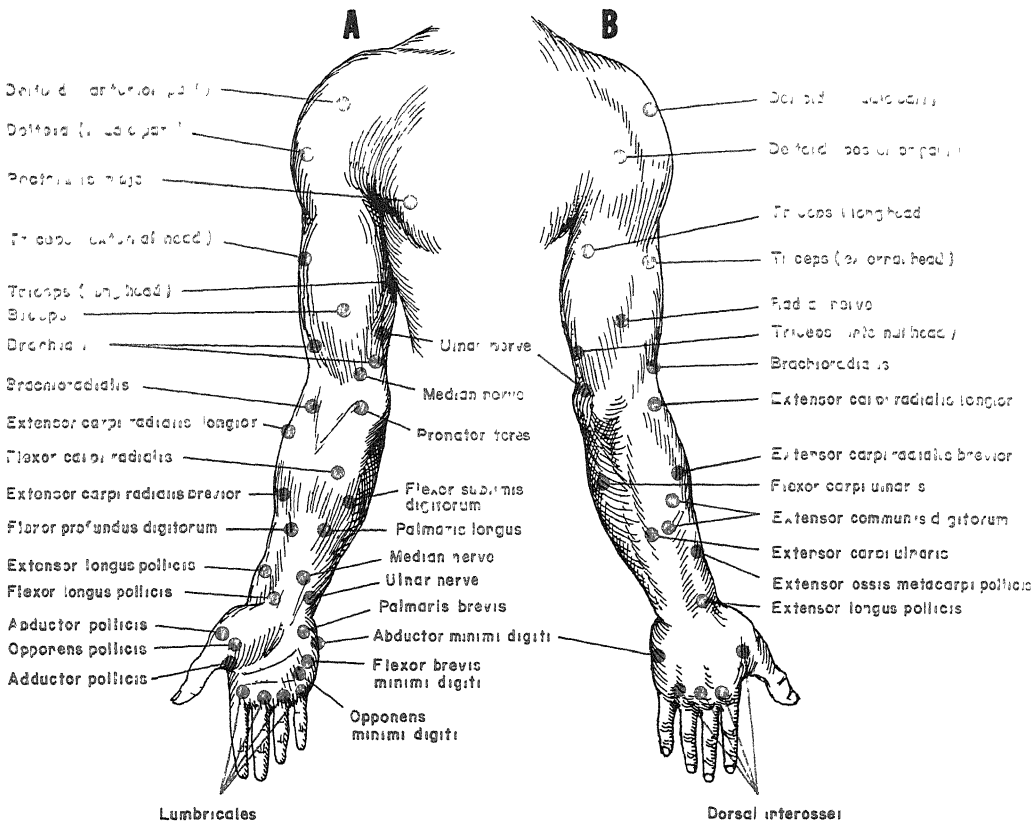

Fig 9 5 Motor points on upper extremity *A* anterior view *B* posterior view Erb cited from Wechsler 1936

cially in areas known as "motor points" where nerves to muscles lie close to the skin (Fig 9 5) Sherrington's experiments using tibialis anticus (previously described) belong to this category of study, the stimulus being delivered to sensory nerves After exposure of the spinal cord by laminectomy, or of the brain by craniotomy, electrodes can be applied to central nervous structures directly This technique is particularly useful for tracing the pathways constituting a system, and thus yields a kind of functional neuroanatomy

Techniques of Stimulation. For several generations of neurologists the stimulating instrument was an induction coil or "inductorium" with a vibrator in the primary circuit to produce alternating current in the secondary Strength was varied by altering the relative positions of the two coils. If a direct rather than an alternating current was desired a battery with a voltage divider was connected through a switch to the tissue, with a device such as a falling weight, a pendulum, or a spring lever arranged so as to open and close switches, and thus to give pulses of known duration Modern stimulators achieve more precise control of frequency, voltage, shape of the voltage or current wave, and duration of each stimulus by use of vacuum tubes or transistors (There is a family resemblance between circuits used in stimulators and those that trigger the sweep of the electronic beam across the screen of a television set) Electrodes, large, small or micro in size, can be applied to the surface or in the depth of the brain by stereotaxic methods On the surface of the spinal cord, on nerve rootlets, or on dissected fragments of rootlets, the electrodes may be applied under either direct or microscopic observation As is the case with a study of injury or ablation, the success of the stimulating technique depends mainly upon skill in examining what is produced by the stimulation Sherrington's results were taken from muscle contractions recorded with levers that measured shortening (for *isotonic* contraction) or tension (for *isometric* contraction) More modern techniques utilize, for example, strain

guages to measure tension, or complex optical systems to measure even the slightest shortening

A relatively new development is stimulation of structures within the brain of human patients in the absence of general anesthesia This was first done by performing the operation under local anesthesia, so that the patient was conscious during the stimulation and could tell the neurosurgeon what he experienced when the stimulus was applied (Penfield and Rasmussen, 1950) Electrodes for this purpose may be manipulated stereotaxically Another but similar technique was developed by Hess (1954) as a device for inserting electrodes through a carrier fastened to the skull (Fig 9 6) Stimulation can be applied without anesthesia, through long, fine wires attached to the electrodes from time to time Or a radio circuit may be employed to transmit without wires to a receiving unit carried by the subject in a collar or harness, with the stimulus applied from a portable unit turned on by the radio signal (Delgado, 1963) The possibility that similar techniques might be used for therapeutic stimulation in human subjects has been considered (Mahl, et al , 1964, Delgado, 1970), with little question that the procedure can be carried out inasmuch as similar devices are now being used with great success as pacemakers for the heart Chronic stimulation of the brain, however, is a somewhat formidable idea because it implies the control of a person's nervous system by someone else This should be noted, therefore, as an example of a scientific procedure that can be made to work technically, but that has not been adopted for general use because of humanitarian or philosophical reservations One should note also that a similar kind of restraint has not been applied to the use of drugs, they are both employed by persons and prescribed by physicians for the sole purpose of altering brain function, often with little attention to possible philosophical objections

Stimulation may be applied by means other than electrical Natural stimulation of sensory receptors may be used, or other types of stimuli may be introduced artificially Thus, thermal, osmotic and chemical stimuli have been introduced into the hypothalamus, brainstem and spinal cord for study of appropriate control systems Drugs may be likewise administered locally by implantation or injection

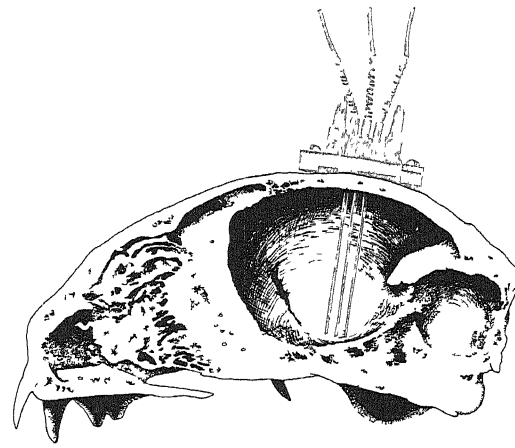

Fig 9 6 Electrode carrier fixed to a sectioned skull to show how insulated electrodes with bared tips can be inserted for stimulation of the brain of a cat without anesthesia The carrier is fixed to the skull during an operation under general anesthesia (Hess 1954)

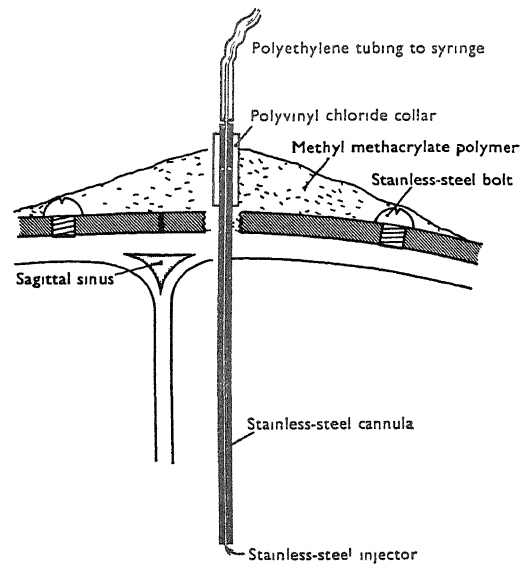

Fig 9 7 Implanted pipette for intracerebral injection of solutions (Epstein et al 1970)

(Fig 9 7) Whereas one drug may act to stimulate a given neural system, another drug may suppress whatever activity may have been present naturally

ELECTRICAL RECORDING

Discovery almost 200 years ago that electricity will stimulate muscle, and that active muscle produces electricity (Galvani, see Mauro, 1969) marked the beginning of parallel

developments in studies of electricity and neurophysiology To detect the presence of an electrical current in muscle Galvani used a nerve to another muscle, activity in the first muscle stimulated the nerve, and hence the second muscle Later authors employed galvanometers of successively improved design, well into this century until Erlanger and Gasser (1937) adapted to their experiments the use of vacuum tubes, amplifiers, and a homemade oscilloscope Modern instruments are solid state descendants of their instruments The important qualities of any recording system are its time constant and its signal to noise ratio (Renshaw et al , 1940) If the amplifier is capacity coupled, with a condenser in series in the input, it will respond quickly to high frequencies but will not faithfully record slow or prolonged wave forms Direct coupled amplifiers, on the other hand, were at first more expensive because of problems of stability and sensitivity, and are somewhat less versatile than the other variety if the strength of the signal is previously unknown Modern instruments, however, are now available commercially with almost any desired characteristics The other property, signal to noise ratio, is important in all electronic instruments. This ratio is significantly greater in amplifiers using transistors than with vacuum tubes, because random electronic processes in tubes produce noise Another consideration in achieving a satisfactory signal to noise ratio is the selection of electrodes that most faithfully gather the potential change in the living system, under conditions where other signals are excluded

Microelectrodes. For early studies of living systems the electrodes were usually metal wires, often platinum or silver, treated so as to minimize polarization of the metal at the point of contact with the tissue Fine tubes or wicks filled with dilute solutions of electrolytes were also used, the electrolytes being those present naturally in extracellular fluid of the animal being studied Woolsey (1958) utilized such electrodes in his studies of the termination of sensory fibers in the cerebral cortex of monkeys When the tubes are fine enough they become micropipettes, and can be utilized for recording potential changes in the neighborhood of single neurons, or even across the cell membrane if a pipette can be inserted inside a cell. In regions where there are generous numbers of large cells, this type of insertion can be accomplished frequently enough to permit studies of changes in membrane potentials associated with stimulation or inhibition of the neuron (Fig 9 8) Many investigators, however, find it more convenient to use sharpened, insulated steel wires as microelectrodes, especially for unit recording from extracellular locations The pipettes used in the experiments of Renshaw et al (1940) had a tip diameter of 15 μ, this measurement is in contrast to sharpened steel needles of some 50 to 100 μ used by Renshaw later (1946), and tip diameters of less than 1 μ for micropipettes of Ling and Gerard (1949) (Fig 9 9)

Electrical Signs of Neural Activity. The fact that electrical changes are associated with neural activity, and the use of electrical or electronic techniques for studying the nervous system, occasionally lead to a confusion that should be avoided The *action potential* is not synonomous with the *nerve impulse*, and the two terms should not be confused As Erlanger and Gasser (1937) phrased it, the action poten-

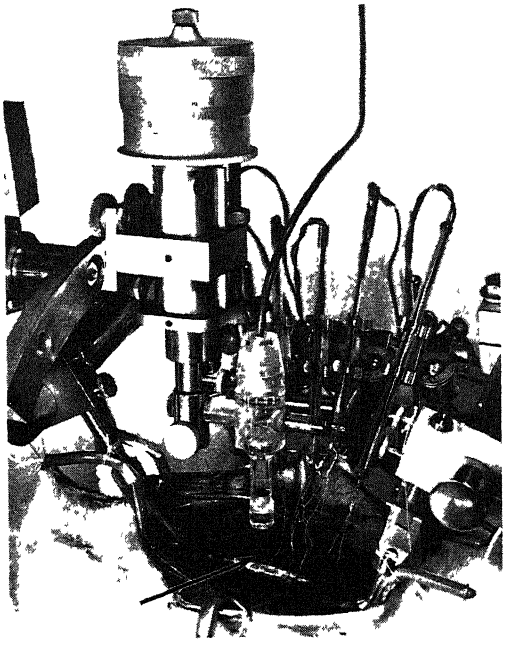

Fig 9 8 Apparatus employed with microelectrodes for intracellular recording from neurons of spinal cord On the left is the rigid frame supportng the micromanipulator the latter carries a preamplifier from which the microelectrode extends (*arrow*) The spinal cord is visible through a pool of paraffin oil that prevents drying of the tissue Other electrodes are for stimulation and other types of recording (Eccles 1957)

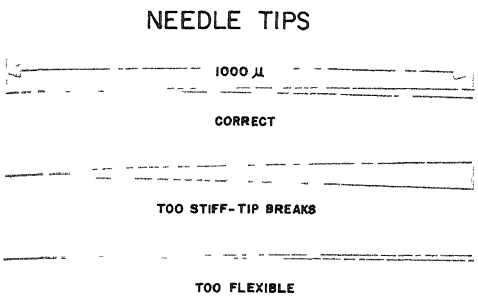

Fig 9 9 Drawing of tips of micropipettes used by Ling and Gerard (1949)

tial is "a sign of nervous activity"—a sequence of potential changes that accompanies the propagation of a nerve impulse What initiates the potential changes is unknown, presumably it is some physicochemical alteration in the membrane of the fiber The fundamental process of the nerve impulse is conduction or propagation of this as yet unidentified change As a result of its propagation along the fiber a wave of sodium penetration is permitted, to be followed in turn by a wave of potassium loss, and then eventually by a wave of restoration of the integrity of the membrane Each of these "waves" is accompanied or signalled by a corresponding potential change and/or current flow

Fundamental processes that enable a nerve fiber to conduct a nerve impulse are presumably the same in peripheral as in central processes of neurons This is in spite of well-recognized differences between fibers within the brain and spinal cord as opposed to those in peripheral nerves (For example, centrally located fibers do not have neurolemma cells, the sheath cells of Schwann The absence of these cells is believed to account for the paucity of effective regeneration of axons in spinal cord and brain) Nevertheless, any recording of action potentials from fibers in spinal cord or brain is believed to include the prepotentials, spikes, and after potentials exhibited by peripheral nerves Yet the shape of the waves recorded from central fibers is different from those recorded in the periphery This difference is caused by peculiaries of the recording site For example, potentials recorded from the surface of posterior white columns of the spinal cord do not have the classic form of an action potential because the transmission of potentials electrotonically throughout the volume of the spinal cord at that location converts what would have been a monophasic record into a triphasic wave (Lorente de Nó, 1947, pp 384–477) Furthermore, the fact that many fibers are active at once, and that they conduct electrotonically the potentials of neurons in their neighborhood or even near their endings makes the potential records all the more difficult to interpret These problems also pertain to potentials recorded from the dorsal or from the ventral roots, where the potentials may reflect conduction in a given fiber, or may arise from changes in neurons lying near or in contact with their terminals, or even potentials in the terminals per se It was to provide some resolution of the uncertainty as to the nature of these dorsal and ventral root potentials that microelectrodes were first employed in the spinal cord by Brock et al (1952) (Fig 9 10) Their use has clarified the nature of synaptic transmission (see sect 1, also pages 9-76–9-82, this section)

Transmission of Control

LOCAL CONTROL PROCESSES

In all types of muscle, and in both exocrine and endocrine glands, the proximate mechanism of control is chemical It is the interaction of some compound or ion with constituents of the membrane of the effector cell that eventually causes contraction or secretion In many, but not all instances, an electrical stimulus can mimic the effect of the nerve impulse

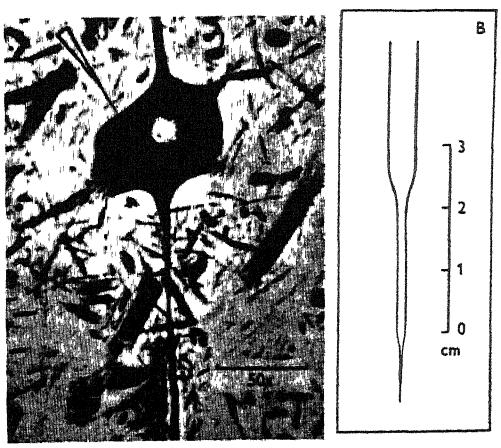

Fig 9 10 Photomicrograph of cat spinal motor neuron and axon (pyridine silver stain), with superimposed tracing of microelectrode tip at same magnification On the right is a scale diagram of the Pyrex microelectrode used in this experiment (Brock et al 1952)

This occurs because electrical currents can bring about physicochemical changes in membranes

If this is true for muscle and gland, is transmission between neurons likewise chemical (or physicochemical)? It is But the truth of this generalization is sometimes obscured by a tendency to describe living systems in physical terms that imply the presence of purely electric or electronic circuits For example, in classical neurophysiology a current is said to "flow" from positive to negative potential sites, whereas in fact any biological potential difference is maintained by differential concentrations of ions, and it is ions moving in or through solutions that carry current The properties of resistance, impedance, conductance, and capacitance as applied to neural systems, and the diagrams that depict membranes as combinations of resistors, condensors, and batteries are only convenient models The resistance of a membrane arises from conditions different from those in a nichrome wire, and the membrane potential is different from the charge stored in a radio condensor Nevertheless, descriptions of the electrical properties of living systems in terms of the properties of macromolecules in watery solutions of electrolytes have been slow to develop What is needed is some way to match the known physical properties of membranes with the molecular and ionic constituents

If proximate control is physicochemical, control at a distance is achieved through an infinite series of similar processes This is, of course, a backhanded way of characterizing a nerve impulse, which is the typical mechanism for neural control at a distance Other types of remote control depend upon the secretion of endocrine glands, the hormones, or other chemicals released into fluids of the body as a result of metabolic processes These, too, induce chemical or physicochemical changes in membranes of cells they control

CODING OF SIGNALS

Approximately 40 years ago Adrian and Bronk (1929) demonstrated that the grading of activity in peripheral nerves depends upon rather simple variables, namely, the frequency of generation of nerve impulses, the interval during which they are generated, and the number of fibers that become active (Adrian, 1935). This means that information is carried from periphery to brain, or from brain to effectors, in the same way as in a digital computer A nerve impulse is one "bit" of information, and is either propagated or not propagated The information carried by a nerve, then, is first of all a function of the number of bits or nerve impulses (Figs 9 11 and 9 12) Another possibility of information transfer is in the patterning of nerve impulses (Bullock, 1967) When a message is sent by telegraphy, for example, the operator does not simply count the number of pulses, he unconsciously analyzes their pattern From dots, dashes, and

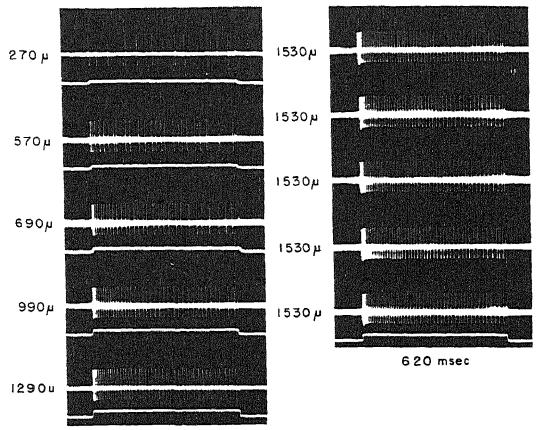

Fig 9 11 Frequency of discharge of single sensory neuron in response to indentation of skin Upper record of each pair is action potentials lower record shows indentation stimulus Depth of indentation is given in micrometers on ordinate From median nerve of a monkey (Mountcastle 1967)

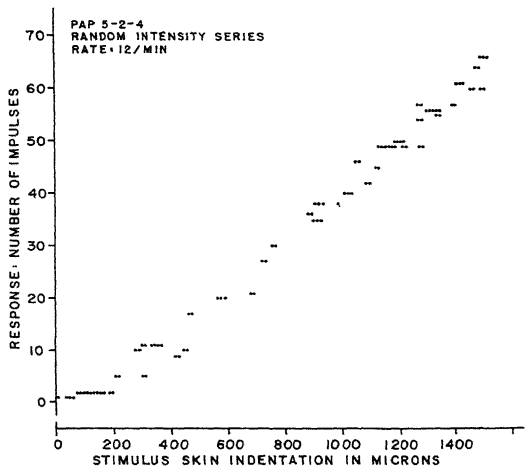

Fig 9 12 Plot of data from experiments such as those of Fig 9 11 Ordinate is derived from the record of nerve impulses Cited from Mountcastle 1967

pauses he recognizes characters of the Morse code A nerve cannot carry the equivalent of a dash, but it can transmit patterns of bits that represent some biological coding It may be that this coding involves a frequency modulation of the impulse pattern, or some other mechanism still more subtle and elegant in its operation (Mountcastle, 1967)

Although transmission of information in the nervous system is digital, mechanisms of computation in spinal cord or brain are more like those of an analogue computer When nerve impulses arrive at a central terminal they bring about quantal, minute release of a transmitter that then creates or contributes to a state that is not unitary, but that can be infinitely graded upon the membrane of the postsynaptic neuron (Fig 9 13) (A similar process occurs at receptors before and while they are stimulated) Whether this change is electrical or physicochemical is not of greatest importance because of the dependence of one on the other, as previously noted What is significant is that the integrative actions of the nervous system are based upon transmission of bits of information, the conversion of bits into time-dependent changes of varied intensity, and finally the influence of this change upon cells or terminals in the region where it occurs Ordinarily this active region is a small locus where the terminal of a nerve fiber lies practically in contact with the membrane of the next element in the pathway

CENTRAL COMPUTATION

The nature of the computational processes at central terminals is being actively studied in many laboratories What may be involved was illustrated long ago in the analyses Sherrington and his associates made of spinal reflexes (Creed, et al , 1932) When they demonstrated that even at the spinal or segmental level the spinal cord contains mechanisms capable of both exciting and inhibiting succeeding neurons in a reflex arc, they gave names to the reactions set up within the spinal cord by the afferent impulses For this purpose they used the analogy of what happens in a nerve when it is stimulated electrotonically, that is, by passage of a direct current Such a current creates a *catelectrotonus* under the negative terminal and *anelectrotonus* under the positive The catelectrotonus is characterized by what has been called a local excitatory state (LES) that is defined as a tendency of the nerve to initiate a nerve impulse in that location The LES has the property of being conducted along the fiber by electrotonic mechanisms rather than by the conducting system responsible for the nerve impulse Consequently, the LES falls off sharply in intensity with distance from the cathode Furthermore, the LES is not an all-or-none phenomenon, in that it can be made stronger by intensifying the current, or weaker when current is reduced Inasmuch as the anelectrotonus under the anode has the opposite kind of properties, one sees that the LES may be said to have either a positive or a negative sign, tending either to excite or to depress excitation of the fiber Finally, when the current is turned off the LES decays exponentially, and is not followed by the refractory state that follows conduction of a nerve impulse

Fig 9 13 Electrical control of frequency of miniature end plate potentials (upper record of each pair) during passage of a current with cathode near the end plate (lower records) Each miniature potential is associated with a quantum release of transmitter although resulting overall effect on postsynaptic membrane is graded in essentially infinite number of steps (del Castillo and Katz cited from Katz 1971)

Using the local excitatory state as a model, Sherrington and his colleagues supposed that an analogous situation is created in the spinal cord by the arrival of impulses via afferent nerve fibers (Fig 9 14) For the changes involved he utilized the terms, central excitatory state (CES) and central inhibitory state (CIS) so as to identify the influence upon the postsynaptic neurons The analogy between LES in the periphery and what happens centrally is clear enough, but there is one significant difference In spinal cord and brain the change having the negative sign, that is, the inhibitory process or CIS, is much more significant than any similar change heretofore discovered in peripheral nerve or receptors of higher animals and man This point cannot be overemphasized

In spite of intensive study, the nature of the

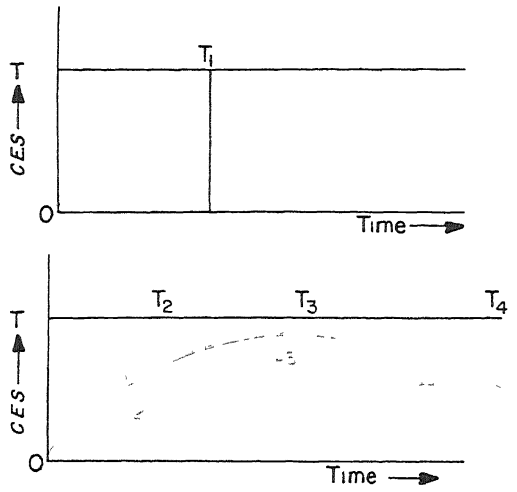

Fig 9 14 Hypothetical time course of central excitatory state (CES) *Upper record* T-T' interval is latent period *Lower record* When a second stimulus is applied at point S_2 S_3 or S_4 after an initial stimulus not strong enough to induce a nerve impulse the latency of the response to the second stimulus depends upon the magnitude of the CES at that time (Creed et al 1932)

CES and CIS remains unknown It is known that they have electrotonic components, as reflected in potentials recorded from either dorsal or ventral roots Barron and Matthews (1938) proposed the hypothesis that the CES is, in fact, a central electrotonic state like peripheral catelectrotonus (Fig 9 15) In their view the CIS is the removal of previously existing CES Eccles (1957) and others have confirmed their observations, and using microelectrodes have recorded changes in transmembrane potentials during excitation and inhibition Nevertheless, there remains much uncertainty as to just how the arrival of nerve impulses in afferent fibers can lead to these alterations in membrane potentials and thus give rise to the potentials that are conducted electrotonically out through the spinal roots

The most popular hypothesis to explain CES, CIS, and the characteristics of synaptic transmission is that the processes are chemical in nature, brought about by discharge of a compound that is released from nerve endings, crosses the minute space to the postsynaptic membrane, there to act upon specialized receptor sites so as to induce changes in membrane potential and in excitability (sect 1, chap 3) Evidence for this opinion is impressive, although indirect In the first instance it is taken by analogy from studies of transmission in peripheral parts of the autonomic nervous system, where acetylcholine, epinephrine, and norepinephrine are known to be responsible for the transmission process The fact that the central nervous system contains these compounds, especially acetylcholine and norepinephrine, and also serotonin (5-OH tryptamine), dopamine (dihydroxyphenylethyl amine) and other compounds known to be active in peripheral systems, plus γ aminobutyric acid (GABA) as a candidate for the role of central inhibitor, is taken as support for the concept that transmission occurs by similar mechanisms both peripherally and centrally Furthermore, the localization of these compounds, where it is known, is in the endings where transmission is initiated (de Robertis, 1964, Peters et al , 1970) Finally, neurons in spinal cord and brainstem can be excited or inhibited by at least certain of these compounds injected into their neighborhood, and typical changes in membrane potential have been reported under these conditions (Grundfest, 1967)

The possibility that the central computational processes are chemical in nature with a variety of substances serving as transmitters is an intriguing one, because it multiplies the number of conceivable types of central control

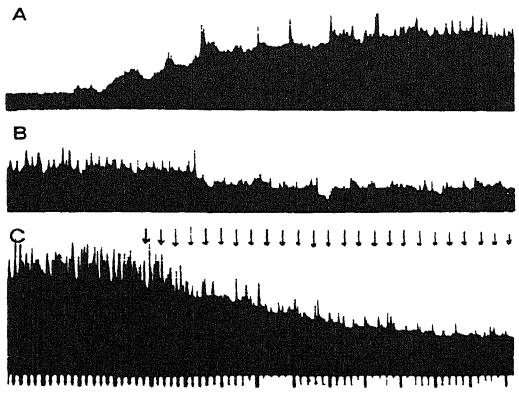

Fig 9 15 Electrotonic and action potentials recorded from anterior rootlet of cat (*A* and *B*) and frog (*C*) Heavy black area at bottom of each record is measure of electrotonic potential on which action potentials are superimposed *A*, imposition of reflex excitatory stimulus *B* addition of reflex inhibitory stimulus *C* Potentials evoked by a weight on foot inhibited by contralateral reflex stimulation at each arrow (Barron and Matthews 1938)

This concept leads to the possibility of selective CES and CIS, in addition to actions that are simply plus or minus With perhaps half a dozen transmitters acting at millions of loci, all having inputs from a variety of downstream loci, the resulting permutations and combinations of circuits offer limitless possibilities for controls and integrative actions

Hierarchy of Control Functions

SIMPLE CONTROLS

There are a few instances where control mechanisms are localized within tissues or organs, and do not require intervention from the nervous or endocrine systems Perhaps the best known example of this in higher animals is the action of acid metabolic products including CO_2 in increasing blood flow through small vessels of active muscle The next higher kind of control is found in invertebrates (see Wiersma, 1967), where reflexes are completed in ganglia that are not a part of the "brain" of the animal In higher animals including mammals there is no clear evidence that this type of ganglionic reflex is possible, although many investigators have tried to establish its presence in autonomic ganglia such as the coeliac and superior mesenteric These efforts have been inconclusive, and the best evidence is that information from detector mechanisms can influence ganglion cells only after transmission to the spinal cord and back to the ganglion via efferent nerves

In a moment the conduct of information to the brain via non-neural routes will be described So far as neural mechanisms are concerned, however, all information brought to spinal cord and brain via nerves arrives through only a few pathways—the dorsal roots of spinal nerves, the fiber tracts functioning as cranial nerves I (olfactory) and II (optic), and afferent fibers in cranial nerves V, VII, IX, and X Similarly, all neural control leaves the brain and spinal cord via either the spinal nerves or the cranial nerves (with the possible exception of nerves I and II) This pattern of neural input and output is common to all vertebrates, what differs among the several phyla, orders and species is the complexity of interconnections between input and output, and hence the complexity of the integrations they are able to sustain.

LEVELS OF CONTROL

From the preceding generalization it follows that one should be able to predict the complexity and variety of possible activities from a knowledge of the number of interneurons and their interconnections (Bullock and Horridge, 1965, p 312) Such a prediction is useful, not only in comparative neurophysiology, but also in comparison of functions of different portions of a single nervous system For example, the spinal cord of lumbar levels seems relatively simple in organization (p 9-21), with segmental mechanisms subserving reflex responses, and with appropriate connections to higher and lower mechanisms But the lumbar cord as confined in the semiflexible vertebral column could not possibly contain the control systems required for a man's walking or running The additional neurons required for such activities are located in the larger parts of the brain, the cerebellum, basal ganglia, and cerebral cortex From this, one can infer the hypothesis that local controls tend to be of the simplest type, with complexity added from higher levels—inasmuch as it is the higher levels that have the extra neurons This principle was explicitly stated by J Hughlings Jackson (1890) in a lecture summarizing his studies of convulsive seizures He identified three levels of control, as follows

"(1) The lowest or first level is roughly and incompletely defined as consisting of cord, medulla and pons, and more completely, and yet still roughly, as being that sensorimotor division of the central nervous system, to and from which pass nerves for every part of the body

"(2) The middle or second level (its motor province) is composed of centres of the Rolandic region (so-called 'motor region' of the cerebral cortex), and, possibly, of the ganglia of the corpus striatum also

"(3) The highest or third level is made up of centres of prefrontal lobes [and] represents most complex movements of all parts of the body from eyes to perineum "

In considering the nervous system 80 years later, one appreciates the clarity with which Jackson perceived this organization, but is inclined to modify it by suggesting the presence of five, rather than three levels, as follows

1) Segmental level, where reflex controls of spinal cord and brainstem do not depend upon

neurons located outside the main sensory, internuncial, and motor columns,

2) Reticular level (named from the reticular formation of the brainstem, see p 9 31), where selective facilitation and inhibition modify both phasically and tonically the activity of segmental reflexes,

3) Level of unconscious control of exchanges, including pulmonary ventilation, water balance, body temperature and energy exchange, and involving mechanisms of brainstem and diencephalon,

4) Level of voluntary control of movement of skeletal muscles and of projection of principal sensory systems—cerebral cortex, basal ganglia, thalamus, and cortico-pontile-cerebellar pathways that give voluntary motion its customary and normal character,

5) Highest level, presumably cortical, where neural activity is not necessarily translated into motion or secretion

The first four of these levels have a common property, each succeeding higher level utilizes mechanisms resident in lower levels Whether this is true of the highest level is not known As many authors have pointed out, one can analyze neural functions only in terms of some response—some output If a response is excluded by definition of the experiment an observer cannot know whether or not neural activity is taking place We know that someone is "thinking" only when he tells us so

NON-NEURAL INPUT SIGNAL GENERATION

Outside, and yet in parallel with, these levels of neural function is another means of communication provided by the blood supply to brain and spinal cord Its significance is sometimes overlooked It is the means by which neural activity can be modified, and probably even initiated, as a result of relatively nonspecific changes extraneous to the pathways of nerve fibers That this can occur has been shown most clearly in the cases of regulation of body temperature, water balance, and pulmonary ventilation Warming the blood, or changing its osmolarity, or altering the pressure of CO_2 seems to activate mechanisms lying in the brain (If the phenomenon is not truly activation, it is at least major modification of neuronal output) Perhaps this only shows that the brain contains specialized detector mechanisms similar to those located in the periphery—for temperature and for taste, for example Nevertheless, the disclosure that neuronal output can be initiated and/or modified by this type of humoral changes raises the possibility that other kinds of changes brought by the blood may have similar actions on other portions of the brain There is evidence that portions of the hypothalamus are sensitive to circulating hormone levels (sect 7, chapts 2 and 9) Perhaps other neurons including those of the cortex have similar sensitivity This may be the manner in which behavior associated with reproduction, for example, is initiated by the central action of sex hormones (Young, et al , 1964)

The output of a neuron that responds to some nonspecific variable such as P_{CO_2}, osmolarity or temperature, is analogous to the performance of an electronic circuit known as a *signal generator* (Strumwasser, 1967) Such a generator may convert a steady, DC voltage into pulses of electrons Circuits to do this are commonplace in electronic devices, including musical electronic organs where the notes may be produced in this fashion by oscillators As defined in this way any detector that responds to a stimulus such as pressure or stretch is a signal generator The output of such a cell is a rhythmic train of nerve impulses Although it is commonplace in sense organs, this type of neuronal activity is not widely recognized in discussions of the central nervous system, where most authors have a tendency to emphasize the stimulus-response relationship dependent upon neural as opposed to humoral or generalized input Perhaps this explains the seemingly endless character of the debate over the question of whether every neural output is a response to some identifiable input That question is most important in its relevance to "voluntary" or "spontaneous" motor activity Can a movement be truly voluntary, or is it necessarily a response to some previous stimulation? If it is true that the central nervous system does contain signal generators, then the question of spontaneous activity takes on a new significance

However this may be, microelectrode recordings from brainstem and hypothalamus reveal what appears to be central detection, and hence signal generation This phenomenon has been utilized to explain the respiratory "drive," and it seems probable that it can be extended also to the waking state, to consciousness, and to forms of behavior that include locomotion, feeding and drinking

Significance of Glia. Intermingled with

neurons in the brain and spinal cord there are other types of cells classified together as glia One species, the *neuroglia*, originates from ectoderm as do the neurons, it is found in two subclasses, the *astrocytes* and the *oligodendroglia* The other, known as the *microglia*, is of mesodermal origin and enters the embryonic brain when it is penetrated by blood vessels (Fig 9 16)

A variety of functions has been attributed to glia, including the supporting of neurons, their nourishment in some trophic manner, and the repair of injury They must contribute to the biochemical and biophysical milieu in which the neurons live (de Robertis and Carrea, 1965, Bodian, 1967, Trachtenberg and Pollen, 1970) In a sense the neurons are subjected on the one hand to shifting concentrations of materials in the plasma and interstitial fluid phases within the brain, and on the other to relatively stable rates of exchanges carried on by glia One interesting possibility is that the constancy of the glia might function as a setpoint for regulations carried on by neurons For example, if the rate of metabolism, and hence of heat production of glia are constant, this might provide a setpoint for regulation of body temperature Theoretically, this idea might be extended also to other chemical and physical properties of the environment of neurons as determined by the glia in their neighborhood

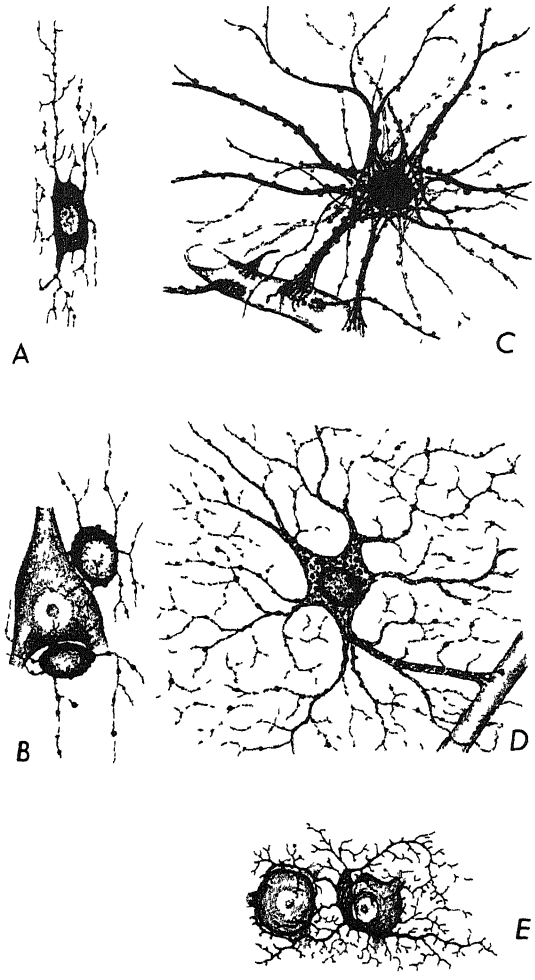

Fig 9 16 Drawings of typical glial cells *A* oligodendrocyte *B* two oligodendroglia lying against a neuron *C* fibrous astrocyte with processes on blood vessel *D* protoplasmic astrocyte *E* microglial cell in vicinity of two neurons From Penfield as reproduced by Copenhaver et al 1971

PRIORITY AND COMPROMISE

If there are many levels of controls and only a few motor outputs, one must ask just how does the efferent component know what it is supposed to do? What determines whether a given set of neurons is employed for posture, for walking, for getting food, for copulation, for building a fire, or for composing textbooks? If the nervous system is considered to be like a telephone system, with the telephone instruments representing sites of both input and output and with exchanges serving connector and computational functions, there at once appears a notable difference between the telephone and the nervous systems When a telephone line is in use, it cannot be secured for another purpose no matter how urgent One can imagine, however, a more elaborate version of a telephone system where a given line becomes available to whatever caller has the greatest need for it, or thinks he has In small towns of 50 years ago the telephone system worked in this fashion, because one could try to persuade the "operator" to interrupt another conversation so as to make a line available for some critical call This is what the nervous system always does, it accommodates itself so as to maintain certain priorities of action, and in doing so often makes compromises Pulmonary ventilation is compromised during speech, especially during singing; energy balance is not maintained during mating in many species, nor during exposure to high environmental temperature in homeotherms But more commonly the compromise is, for example, that mechanisms preserving posture are altered during movement, that activity in an efferent system is suppressed for movement

of its antagonist, that what might become a prolonged movement is converted into a phasic or rhythmic alteration In this sense there is a hierarchy among even spinal reflexes, with some serving higher integrations than others (Sherrington, 1906) Nevertheless, even the compromises are brought about, and priorities are established, by means of the CES and CIS evoked in central mechanisms as a result of incoming neural activity, or in response to information transmitted via the blood stream It is the characteristic localization, distribution, and intensity of the CES and CIS that is essential for every variety of central neural activity, even the most elaborate, intricate, or subtle

Control vs Regulation

DEFINITIONS AND EXAMPLES

Thus far in this chapter the word *control* has been used in its common English meaning This same meaning, however, can have a technical significance if control is distinguished from a related word, *regulation* In physiology the latter implies more than the former, because it is used by many authors to signify that controls tend to preserve some almost constant condition For example, the action of the heart is controlled, in part by nerve fibers from the vagus and from sympathetic nerves But blood pressure in the aorta is regulated, because these and other control systems keep it at an almost constant level There are a very few instances in physiology where a constancy may occur solely as a result of interaction of physical forces This happens, for instance, when a resting, fasted man is exposed without clothing to an environmental temperature of about 28° C Under these stated conditions his "basal" rate of heat production will equal his rate of heat loss to the 28° C environment Usually, however, a constancy of a physiological variable requires a feedback mechanism that takes information about the output back to the control system so as to modify the nature of the control Feedback loops are well known in mechanical and electrical devices The governor on a steam engine, a thermostat controlling a furnace, as well as the control of an air conditioner all depend upon feedback loops In driving a motor car at a constant speed, watching the speedometer is the feedback component of the control system Analogous mechanisms generate regulations in living organisms Lavoisier (see Adolph, 1961) and Claude Bernard (1878) long ago recognized that life depends upon these regulations, and that they function to maintain a relative constancy of composition of the fluids of the body They also maintain other constancies, including body temperature, and have profound effects upon behavior through their ability to direct and even to dominate the activity of all parts of the neural and endocrine control systems

According to this concept, then a *regulation* utilizes control systems to achieve a relative constancy as a result of *detection* of some variable and the interposition of a *feedback loop* between output and input (Fig 9 17)

Because skeletal muscle contains detectors that initiate a feedback of information to the spinal cord, one may ask whether the action of skeletal muscles is regulated or controlled It is a regulation that prevents slackness of muscles, either at rest or during movement Through feedback from muscle spindles (p 9-82), and with the collaboration of γ efferent fibers back to the spindles, each muscle is maintained at a length appropriate to the position of the joint it moves With reference to the control of movement, however, the concept of regulation becomes less applicable, in part because of problems that arise in the analysis of a dynamic (as distinct from a static) condition One can identify the possibility of regulation of motion in a soaring bird, perhaps, or in a fish maintaining its place in a moving stream, or in the unconscious standing posture of almost any subject The rigid caricature of standing seen in a decerebrate animal in a laboratory (p 9-101) is often given as an example

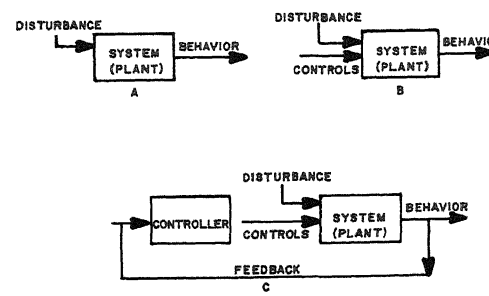

Fig 9 17 Development of feedback control patterns *A*, uncontrolled system *B*, open-loop control *C* closed-loop control with feedback Grodins, in Yamamoto et al 1969

of a postural regulation, maintained by feedback mechanisms from stretch receptors, joint receptors, and the labyrinths, acting upon control systems in the brainstem Nevertheless, the concept of regulations is not yet ready to try to account for the fleeting, shifting, fluid movements of a cat's normal gait

There is, however, another very interesting relationship between the concept of regulation and voluntary movements These movements are utilized in regulation of body temperature, drinking, food intake, and even in pulmonary ventilation It is possible voluntarily to alter a given regulation for a brief period of time, although at the risk of inducing air "hunger," thirst, or sensations of chilling or overheating Ordinarily the regulation will be reinstated and the voluntary disturbance will be counteracted Conversely, regulations often alter voluntary activity—in fact, the dominance of the body's regulations over many forms of voluntary activity seems to be a condition required for preservation of life of an individual as well as of a species

SETPOINT

When controls produce a regulation with some constant value, one wonders how the system "knows" what this value should be Moreover, in many biological systems the value changes from time to time, for example, normal body temperature is lower than the temperature of a working individual, while in fever a completely different level may be maintained (Hammel, 1965) In engineering systems a setpoint requires the generation of some type of constant signal against which the feedback signal may be compared Whether the nervous system is capable of generating such a reference signal is a problem of considerable interest (Hardy, 1965) In biological systems there is another possibility, however, that has a significance different from the conventional idea of a setpoint Consider the circulation and regulation of blood pressure It is conceivable that the upper limit of aortic blood pressure is determined merely by the sensitivity of stretch receptors in the carotid sinus and arch of the aorta If the pressure goes high enough to stimulate the receptors, reflexes will be initiated to lower the pressure The higher the pressure the more active the receptors, and thus the more powerful the reflex responses to bring the pressure down Similarly, if there is somewhere in the body a detector that responds to a reduction in blood pressure, with a threshold of hypotension at which it becomes active, reflex controls to raise pressure can be set into action under this set of conditions In this model the nervous system that does the regulating is not required to contain a generator for a setpoint, the constancy of pressure being a result of the alternate action of hypertensive and hypotensive detectors and the controls they bring into play Thus, conceptually the inherent sensitivity of the detectors replaces the setpoint generator It follows that according to this model the level at which the constancy is preserved is a function of the sensitivity of the detectors Survival of a species shows that the essential detectors for all of the vital regulating systems have sensitivities in the appropriate range

A final word may be added about how detectors acquire and maintain this particular sensitivity In mammals it seems likely that their sensitivity is determined by the composition of the environment in which they develop The detectors of the fetus are exposed to compositions determined by the mother's detectors There is reason to believe that detectors have an intrinsic property of showing least activity when the variable to which they respond has a value that is unchanging This phenomenon is known as *adaptation* in nerve endings (sect 8, chap 1) or as *accommodation* in nerve fibers (sect 1, chap 3) It may be that chemoreceptors in the fetal arterial system, for example, acquire a sensitivity that reflects in some measure the CO_2 and O_2 pressures in the system in utero at the stage when these control reflexes became specialized Alternatively, their sensitivity might be determined in the neonatal period as a kind of physiological imprinting In any event, there presumably is a continuity of controls and regulations from one generation to another on a genetic basis that in itself might be the means of determining sensitivity of the critical detectors

2 ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

General Considerations

All parts of the nervous system of mammals including man originate either from the neural tube or from the neural crest of the embryonic ectoderm The *neural crest* gives rise to the neurons whose cell bodies are located in dorsal root ganglia and homologous ganglia on cranial nerves, it also produces the postganglionic neurons of the autonomic motor system (Fig 9 18) The *neural tube* acquires landmarks that permit the spinal and cranial portions to be distinguished as early as the 3rd week in a human embryo Nevertheless, even in the adult there is no significant difference in structure between the medulla oblongata just above and the spinal "medulla" or cord just below the foramen magnum Distinction between the two is based on anatomic relations rather than on any unique feature of their organization

EMBRYOLOGY OF THE BRAIN

The cranial part of the neural tube becomes further demarcated into a series of five "vesicles," or fluid-containing swellings, that eventually produce the neurons of every part of the brain How the brain develops from these vesicles, where neurons of the several parts come from, and especially how it flexes upon itself (Fig 9 19) and comes to occupy the space available in both anterior and posterior fossae are fascinating topics, albeit too detailed for consideration here Briefly, the cerebral cortex becomes more and more voluminous as it differentiates with its underlying fibers and basal ganglia, until the cortex comes to envelope the brainstem as rising bread dough may completely overflow and eventually hide the pan in which it was mixed To a lesser degree a similar expansion occurs in the cerebellar vermis and cortex It is this overgrowth of the cerebral cortex in every direction that explains certain puzzling relations (Fig 9 20) For example, if a cadaver brain is sliced in the coronal plane, the section may disclose a number of apparent cavities or spaces (Fig 9 33, below) These may include the body of the lateral ventricle, its inferior horn in the temporal lobe, the third ventricle, and perhaps the foramen of Monro connecting it on either side to the lateral ventricle The puzzle, however, is the presence of a cleft that lies between the lateral and third ventricles, but that is separate from both of them It is the transverse fissure of the cerebrum, continuous with the subarachnoid "space" that everywhere surrounds the surface of the brain, and a token here of how the diencephalon has been "buried" by overgrowth of the telencephalon

NOMENCLATURE

Names used to designate the several major portions of the central nervous system usually describe their appearance or their anatomical relations Fiber tracts are known eponymically after the anatomists who discovered them, or more precisely are given the names of the parts they join—the corticospinal pathway, for example Another type of designation comes from the five embryonic brain vesicles, and lends itself to the concept of levels of function as presented in the preceding chapter In this terminology the origin and level of each of the major components may be summarized as follows

Telencephalon (end brain)
- Cerebral cortex
- Central white matter of the cerebrum, corpus callosum, internal capsule
- Basal ganglia claustrum, caudate nucleus, globus pallidus, putamen, amygdala
- Hippocampus

Diencephalon ("in between" brain)
- Thalamus
- Hypothalamus
- Epithalamus pineal gland, stria medullaris, habenular region and related structures

Metathalamus medial and lateral geniculate bodies
Subthalamus (ventral thalamus)
Mesencephalon (middle brain)
Corpora quadrigemina (superior and inferior colliculi)
Cerebral peduncles, substantia nigra
Tegmentum of mesencephalon
Metencephalon ("after" brain)
Cerebellum—cortex and nuclei
Tegmentum of pons
Pons
Myelencephalon (marrow brain)
Medulla oblongata

Much of the material that students are expected to learn in neurophysiology is, in fact, applied neuroanatomy Courses in the latter subject usually include information about function, because structure and function are necessarily linked, and learning one aids in remembering the other For this same reason an account of how the nervous system works and what it does cannot omit certain details of how it is put together Consequently, a brief review of the major components of the central nervous system and their connections is given in this chapter Students who have previously studied neuroanatomy can well afford to go directly to Chapter 3 For additional information about the anatomy of the system, Truex and Carpenter (1969) may be utilized, or another similar textbook Clarke and O'Malley (1968) have published a most valuable collection of citations to classic work in neurophysiology and anatomy

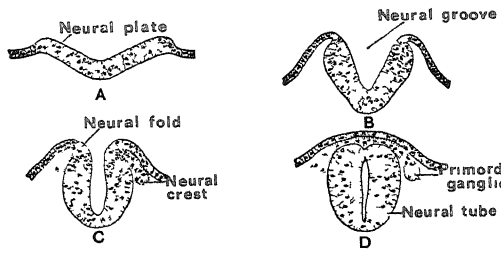

Fig 9 18 Development of neural tube and ganglia from ectoderm of neural plate and neural crest in human embryo (Arey 1965)

STRUCTURE AND RELATIONS OF THE SPINAL CORD

The *gray matter*, centrally placed, is composed of a mass of nerve cell bodies and nerve fibers (dendrons and axons), mostly unmyelinated, supported by a framework of neuroglia It is well supplied with blood vessels In the ventral columns are situated the large, multipolar bodies (100 μm in diameter) of the α motor neurons whose axons leave the cord by the ventral roots (Fig 9 21) Each axon ends on a group of skeletal muscle fibers—the neuromuscular structure constituting the so-called motor unit The small or γ cells of the ventral columns innervate the intrafusal fibers of muscle spindles, and thus control the threshold of these important proprioceptive end-organs In the thoracic and upper lumbar segments, the gray substance lying between the ventral and dorsal columns shows a small lateral projection This is the lateral column or horn, it contains a cluster of nerve cells (the *intermediolateral cell column*) that give origin

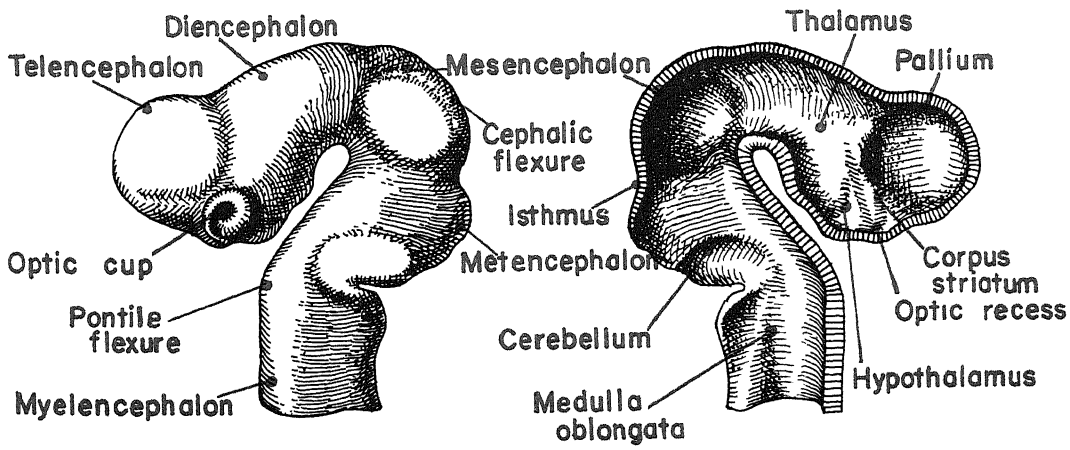

Fig 9 19 External and internal views of vesicles of embryonic human brain His Prentiss-Arey from Ranson and Clark 1959

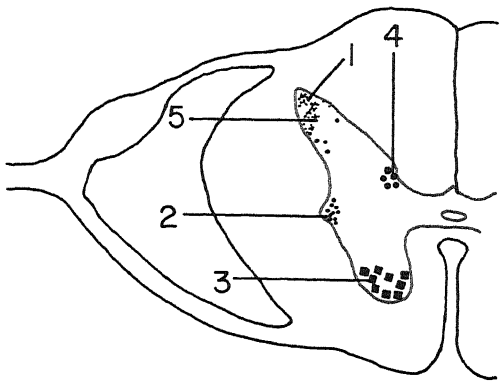

Fig 9 21 Location of principal cell groups in grey substance of thoracic spinal cord

to the preganglionic, autonomic fibers which also leave the cord via the anterior (ventral) nerve roots Functionally these cells are connector or internuncial neurons The well-defined collection of cells occupying the inner part of the base of the posterior horn is known as *Clarke's column*, this group, since it is confined almost entirely to the thoracic region of the cord is also known as the *dorsal nucleus* It is homologous with the nucleus cuneatus of the medulla oblongata To the outer side of the base of the posterior column is an area where strands of white matter and prolongations from the main mass or gray matter intermingle to form a delicate interlacement This is known as the *reticular formation* (formatio reticularis) and is most prominent in the cervical region It is continuous with the reticular formation of the medulla oblongata and pons At the apex of the dorsal horn is a cap of what appears to be gelatinous material containing groups of small nerve cells possessing many dendrites and named the *substantia gelatinosa of Rolando* It is believed to receive the finest fibers (myelinated and unmyelinated) of the posterior roots, and rostrally is continuous with a sensory column of the fifth nerve, the "spinal nucleus" The remaining part of the substance of the dorsal horns constitutes the *chief sensory nucleus* The bar or isthmus connecting the two lateral masses of gray matter across the midline contains the *central canal*, derived from the enclosed cavity of the embryonic neural tube, it is continuous with the ventricular system of the brain The parts of the gray isthmus in front of and behind the central canal are referred to as the *anterior* and *posterior gray commissures*, respectively

The surrounding *white matter* is composed of bundles of fibers both myelinated and unmyelinated, the former predominating Each half of the spinal cord is marked out by the fibers of the ventral and dorsal nerve roots into three white columns or *funiculi—ventral* (an-

terior), *lateral* and *dorsal* (posterior) The band of white matter lying in front of the gray commissure is called the *anterior* (ventral) *white commissure*

The Spinal Nerve Roots

There are 31 pairs of spinal nerve roots, a pair from each spinal segment The anterior and posterior roots join within the vertebral canal just beyond the posterior root ganglion to form a corresponding number of spinal nerves

The *anterior roots* of the spinal nerves are composed entirely of efferent fibers These are the α and γ myelinated fibers to skeletal muscle, and also, in the thoracic and lumbar regions, the fine, lightly myelinated preganglionic fibers of the autonomic nervous system The *posterior roots* are constituted of afferent fibers from the skin, muscles, and viscera They are the central processes of the unipolar cells of the spinal ganglia There is no important evidence that they contain efferent fibers The generalization that the dorsal roots are afferent and the ventral roots efferent in function is called the *Bell-Magendie* law Two divisions of the posterior root, a medial and a lateral, are distinguished The lateral division is largely composed of small unmyelinated fibers, these, after entering the cord form the small triangular area at the tip of the posterior horn known as Lissauer's tract The fibers of the medial division enter the posterior columns of the cord (see Fig 9 22)

SEGMENTAL DISTRIBUTION OF THE SPINAL NERVES

In the young mammalian embryo and in certain adult lower forms, e g , fishes, the body is demarcated into a regular series of transverse segments or *metameres* The muscles (*myotomes*), skin (*dermatomes*) and viscera of each of these primitive blocks receive innervation from the nerve roots of a corresponding spinal segment The anterior root of each spinal nerve supplies motor fibers to the respective myotome, and autonomic fibers to the viscera and skin, the posterior root supplies sensory fibers to the corresponding dermatome as well as to the muscles and viscera In mammals, as a result of the outgrowth of the embryonic limbs the orderly arrangement of the metameres from before backwards becomes altered In the body of the adult, the primitive meta-

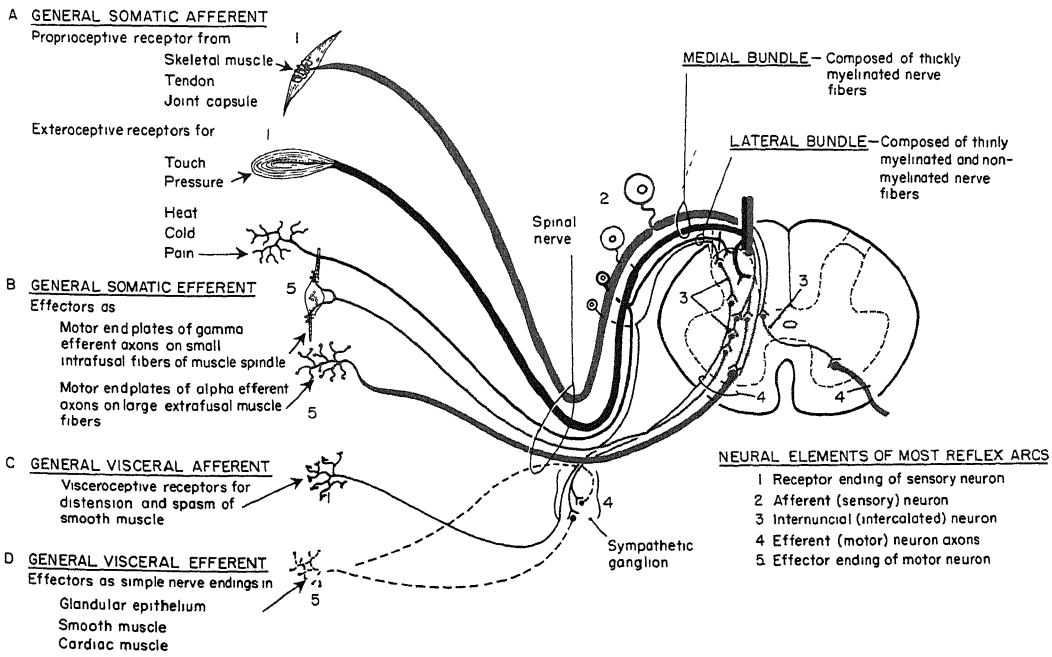

Fig 9 22 Diagram of functional components of a thoracic spinal nerve showing distribution of dorsal root fibers as they enter the spinal cord Skeletal muscle afferent and efferent fibers are shown in brown Numbers identify elements as listed at lower right From Truex and Carpenter 1969

meric disposition is observed only in the trunk An apparent segmentation is present, nevertheless, in the spinal nerves because they exit between pairs of vertebrae But then as their fibers take their courses to or from the limbs, they form the brachial and lumbosacral plexuses and, after intermingling freely, issue again as the peripheral nerves The latter, in consequence, are composed of fibers derived from two or more spinal segments, and fibers from a given segment pass into several peripheral nerves The muscles supplied by a given spinal segment do not necessarily lie adjacent to one another (the coracobrachialis, for example, is innervated by the same segments as those which supply the muscles of the thumb) and a single muscle may derive its nerve supply from more than one spinal segment As development proceeds and the limbs grow out from the trunk, the dermatomes become arranged in a series of narrow areas lying for the most part in the long axis of the limb (Fig 9 23) The skin and muscles of the limbs also tend to move away from the visceral structures with which they were originally associated and, in the adult, structures innervated by a common spinal segment may be widely separated Thus, the diaphragm is innervated (through the phrenic) from the 3, 4, and 5 cervical segments which also supply skin and muscle in the region of the neck and shoulder The heart receives sensory and autonomic fibers from the upper thoracic segments, these segments also supply sensory fibers to the skin over the inner aspect of the arm and hand and upper part of the thorax This topic will be considered further in its relation to the phenomenon known as referred pain

Several methods have been employed by different investigators in mapping out the dermatomes in animals and in the human subject The *anatomical* method is laborious and consists in tracing the fibers of a spinal root to their terminations in the skin A *physiological* method ("isolation" or "sensory remainder" method) was employed by Sherrington in cats and monkeys The area of skin supplied by a given segment was demarcated by dividing at least two of the sensory roots above and two more below it The region supplied by the uncut root was revealed as a sensitive area of skin bounded above and below by an anesthetic zone supplied by the cut fibers (No anesthesia follows cutting of the dorsal root fibers of a single spinal nerve, because of overlap from adjacent segments) Foerster (1933) used similar methods to map out the dermatomes in man He also stimulated the posterior roots at operation, and used the resulting vasodilatation as a means of demarcating dermatomes Similar maps were prepared by Head (1893) from studies of cases of herpes zoster, a condition due to a viral infection of cells, usually in a single dorsal root ganglion

The Tracts of the Spinal Cord and Brainstem

Fiber tracts of the cord are divisible into two main groups *a*) *Long tracts*, both ascending and descending, connect the cord with other parts of the central nervous system *b*) *Short tracts* (intersegmental or association tracts, ground bundles) begin and end within the spinal cord and connect different segments The fiber tracts making up the substance of the respective funiculi are shown diagrammactically in Figure 9 24

SUMMARY OF FUNCTIONS OF PRINCIPAL ASCENDING TRACTS

A) Fibers Mediating Conscious Sensations. *1*) Fibers mediating thermal and painful sensations are part of the lateral divisions of the posterior nerve roots, and enter *Lissauer's*

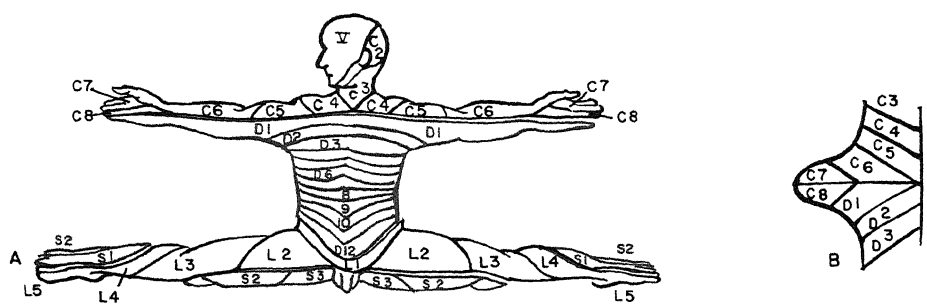

Fig 9 23 *A* Levels of the spinal cord from which various areas of the surface of the body receive sensory innervation *B*, Diagram to show how development of limb bud alters dermatomal representation

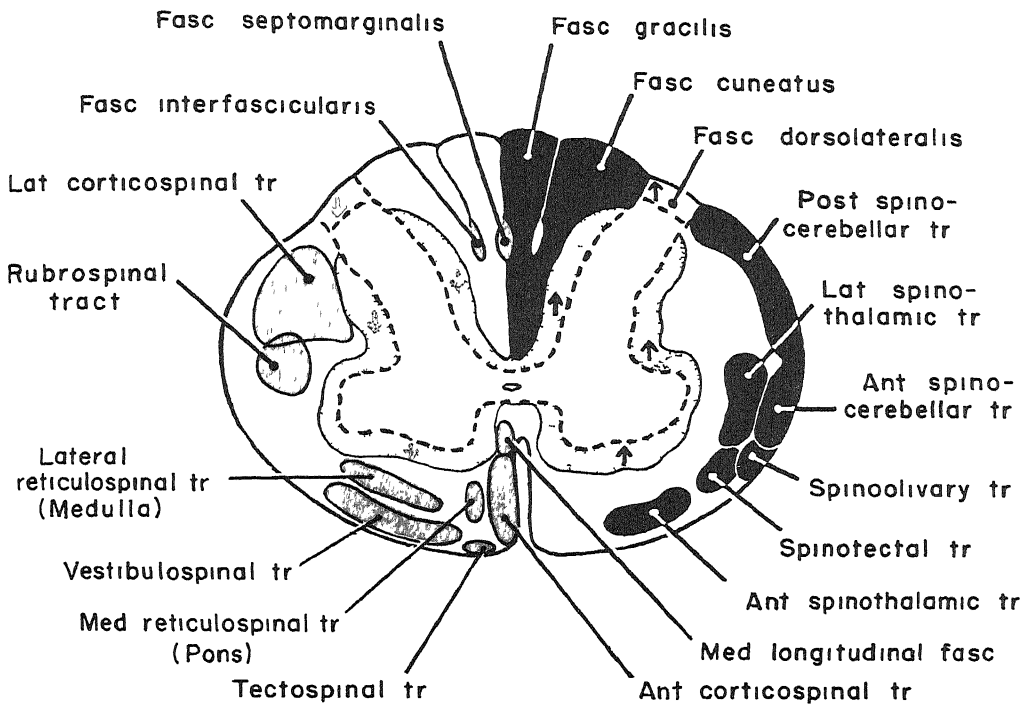

Fig 9 24 Location of major spinal pathways Ascending pathways are shown on the right in black descending paths are on the left in brown The fasciculus proprius system (*stippled*) and dorsolateral fasciculus contain both ascending and descending fibers From Truex and Carpenter 1969

tract of the spinal cord Immediately, or after a very short upward or downward course, they enter the dorsal horn and connect with second order neurons having axons that cross to the opposite side in the white commissures and ascend as the *ventrolateral spinothalamic tract* This tract occupies a position in the brainstem lateral to the medial lemniscus and ends in the posterolateral part of the ventral nucleus of the thalamus (Fig 9 25)

2) The fibers conveying all other sensory impulses, e g , from muscles and joints (sense of movement and position), and those mediating the senses of vibration, touch, pressure, tactile localization, and spatial discrimination enter the cord in the medial division of the posterior roots and ascend in the *fasciculus gracilis* and *fasciculus cuneatus* The fibers mediating all of these sensations (except for some in the ventral spinothalamic tract concerned with touch and probably with tactile localization) pass without crossing to the nuclei of these fasciculi in the medulla oblongata, where they connect with secondary neurons The axons of the latter constitute the *internal arcuate fibers*, they decussate with those of the opposite side and ascend to the thalamus as the *medial lemniscus* Tertiary neurons convey the impulses from thalamus to cerebral cortex

B. Sensory Pathways That Do Not Reach the Cortex Impulses from receptors in muscles, tendons, and joints, as well as some from tactile receptors that are not destined to reach the thalamus and cerebral cortex are conveyed into the spinal cord by fibers composing the medial divisions of the posterior roots These fibers connect at once with cells of *Clarke's column* and are continued upwards in the *dorsal* (direct) and *ventral* (indirect) *cerebellar tracts* of the same side, mainly, but also of the opposite side Some of these impulses, viz., those which enter the cervical cord, are conveyed by fibers of the cuneate fasciculus to the cuneate nucleus, to be relayed by secondary neurons (*external arcuate fibers*) via the inferior peduncles to the cerebellum (Fig 9 25)

SENSORY DISABILITIES FOLLOWING LESIONS

In a *transverse spinal lesion* interrupting solely the posterior fasciculi, vibratory and position senses are lost but the sensation of touch is retained, since the fibers which have entered the gray matter and crossed below the level of the lesion to ascend in the ventral spinothalamic tract have escaped injury Like-

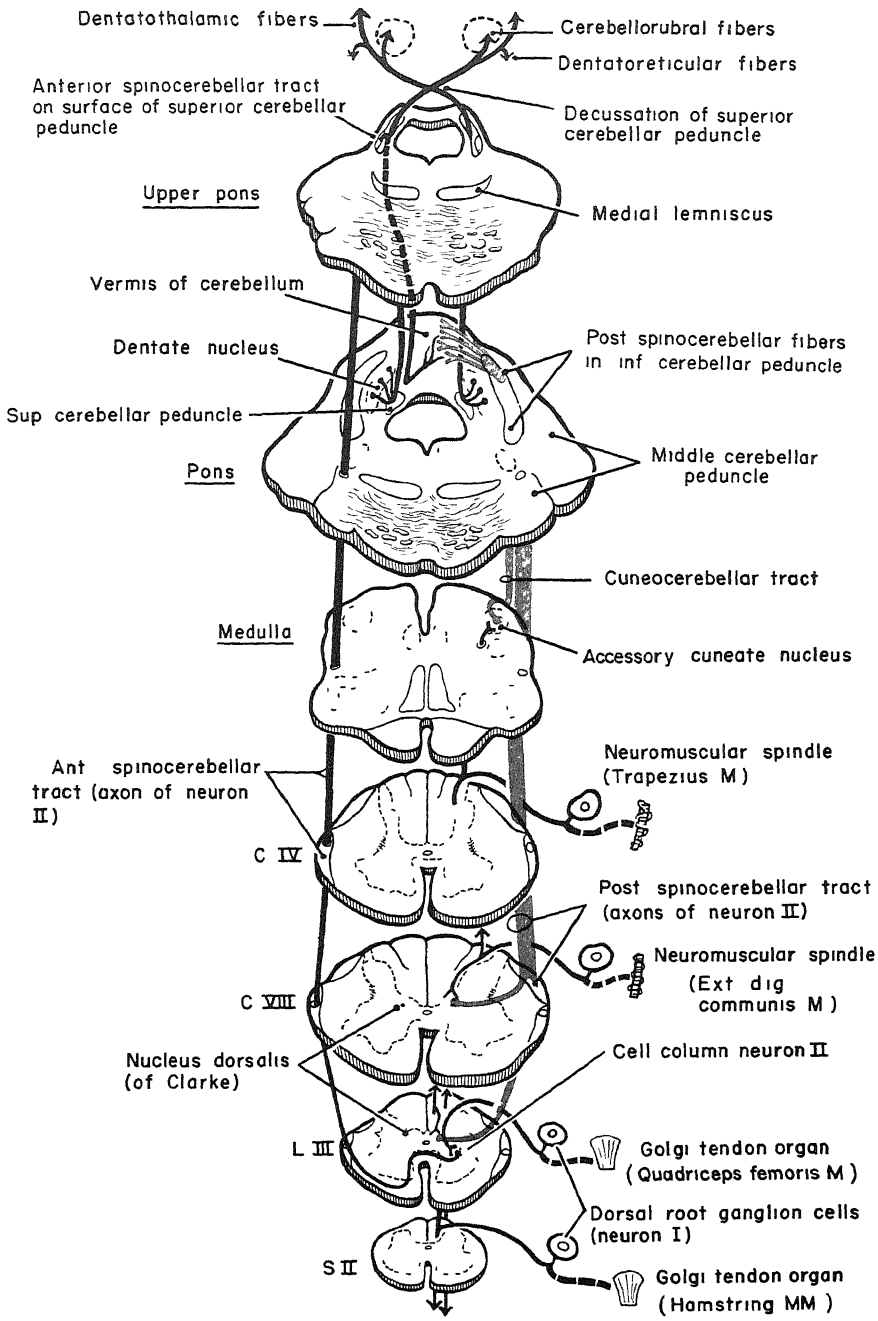

Fig 9 25 Proprioceptive pathways ascending from spinal cord through brainstem with connections in cerebellum pons and on to thalamus Spinal levels are indicated on the left From Truex and Carpenter 1969

wise, although a *hemisection of the spinal cord* destroys vibratory and position senses on the same side and pain and temperature sensibilities on the opposite side it does not abolish tactile sensibility as this is conveyed in both crossed and uncrossed pathways

A lesion in the *lower part of the brainstem* may involve one of the sensory pathways exclusively of the others Thus, an injury localized to the outer part of the lower pons or of the medulla oblongata by injuring the spinal lemniscus may cause loss of sensation to pain,

heat, and cold over the *opposite half* of the body and leave muscle sense and tactile discrimination intact Sensory loss of this nature accompanied by ipsilateral cerebellar symptoms occurs as a result of the occlusion (as by thrombosis or embolism) of the *posterior inferior cerebellar artery* Usually also, as a result of the involvement of the bulbospinal tract of the trigeminal nerve the face on the same side as the occluded vessel shows a loss of pain and temperature sensibilities whereas tactile sensation which is transmitted by the main sensory nucleus is largely unaffected A lesion more centrally placed may, by implicating the medial lemniscus alone, cause the converse type of dissociated sensory defect, namely, loss of the sense of position of the limbs and of spatial discrimination with retention of sensibility to pain, heat, and cold In lesions at higher levels in the brainstem all forms of sensation are likely to be involved more or less equally

DESCENDING TRACTS OF SPINAL CORD AND BRAINSTEM

1) Corticospinal (Cerebrospinal) Tracts. From their origins in the cerebral cortex these tracts descend through the cerebrum, through the internal capsule on each side, the crus cerebri of the mesencephalon, the pons of the metencephalon, and the pyramid on the inferior surface of each side of the medulla oblongata (Fig 9 26) At the lower border of the medulla each tract divides into two bundles of unequal size, the larger of which crosses to the opposite side and descends in the posterior part of the lateral funiculus of the cord as the *lateral corticospinal tract* The remaining fibers uncrossed, descend in the anterior funiculus as the *anterior corticospinal tract* In most instances the direct or anterior corticospinal tract is but a small part of the total number of corticospinal fibers (usually not over 10%), but the number of fibers in the anterior tract varies and in rare instances most of the corticospinal fibers lie in this position In most cases these anteriorly placed fibers descend only as far as the upper thoracic spinal cord Even these fibers cross to the opposite side before terminating on the ganglion cells of the anterior gray column There are also direct corticospinal fibers lying in the lateral columns of the spinal cord which do not cross to the opposite side Through these the precentral motor cortex sends impulses to ipsilateral skeletal muscles

All corticospinal fibers whether crossed or uncrossed connect with the large motor cells of the ventral gray columns (anterior horn cells) The connections are of two types, *a*) direct synapses (20 to 30%) with the motor neurons, *b*) indirect connections with these cells through an internuncial neuron whose cell body is also in communication with a posterior root fiber on each side It has been estimated that from 75 to 90% of the corticospinal fibers terminate in the cervical (55%) and thoracic (20%) regions of the spinal cord, and about 25% in the lumbar and sacral regions

For many years an erroneous belief was entertained that all of the fibers in the pyramids on the ventral surface of the medulla oblongata arose from the Betz cells of the precentral gyrus and were responsible for all voluntary activity of the skeletal musculature It is now known that this concept contains many errors Only a very small percentage of the corticospinal fibers arise from the gigantic Betz cells of the precentral gyrus, approximately 3 to 4% The remainder of the corticospinal fibers arise from other cells in the precentral gyrus, from cells in the parietal cortex and perhaps other areas There is a question as to whether all of the fibers in the medullary pyramids are of cortical origin, and some investigators have even questioned whether they are all descending fibers Certainly, all voluntary muscular activity is not achieved exclusively by corticospinal fibers nor by fibers contained in the medullary pyramids There are multisynaptic fiber pathways from the cortex down to the anterior horn cells of the spinal cord, which are also capable of producing voluntary movement

2) Corticobulbar Fibers. The fibers passing from the lower part of the motor area of the cortex to the cranial nuclei constitute the important *corticobulbar tract* These bear precisely the same relationship to the cells of the cranial motor nuclei as does the corticospinal tract to the anterior horn cells of the cord The corticobulbar fibers, however, cross at various levels throughout the brainstem The location of these fibers and the corticospinal systems in the internal capsule is considered in the following section on the telencephalon

3) Vestibulospinal Tracts. Two tracts, a ventral and a lateral, are commonly desig-

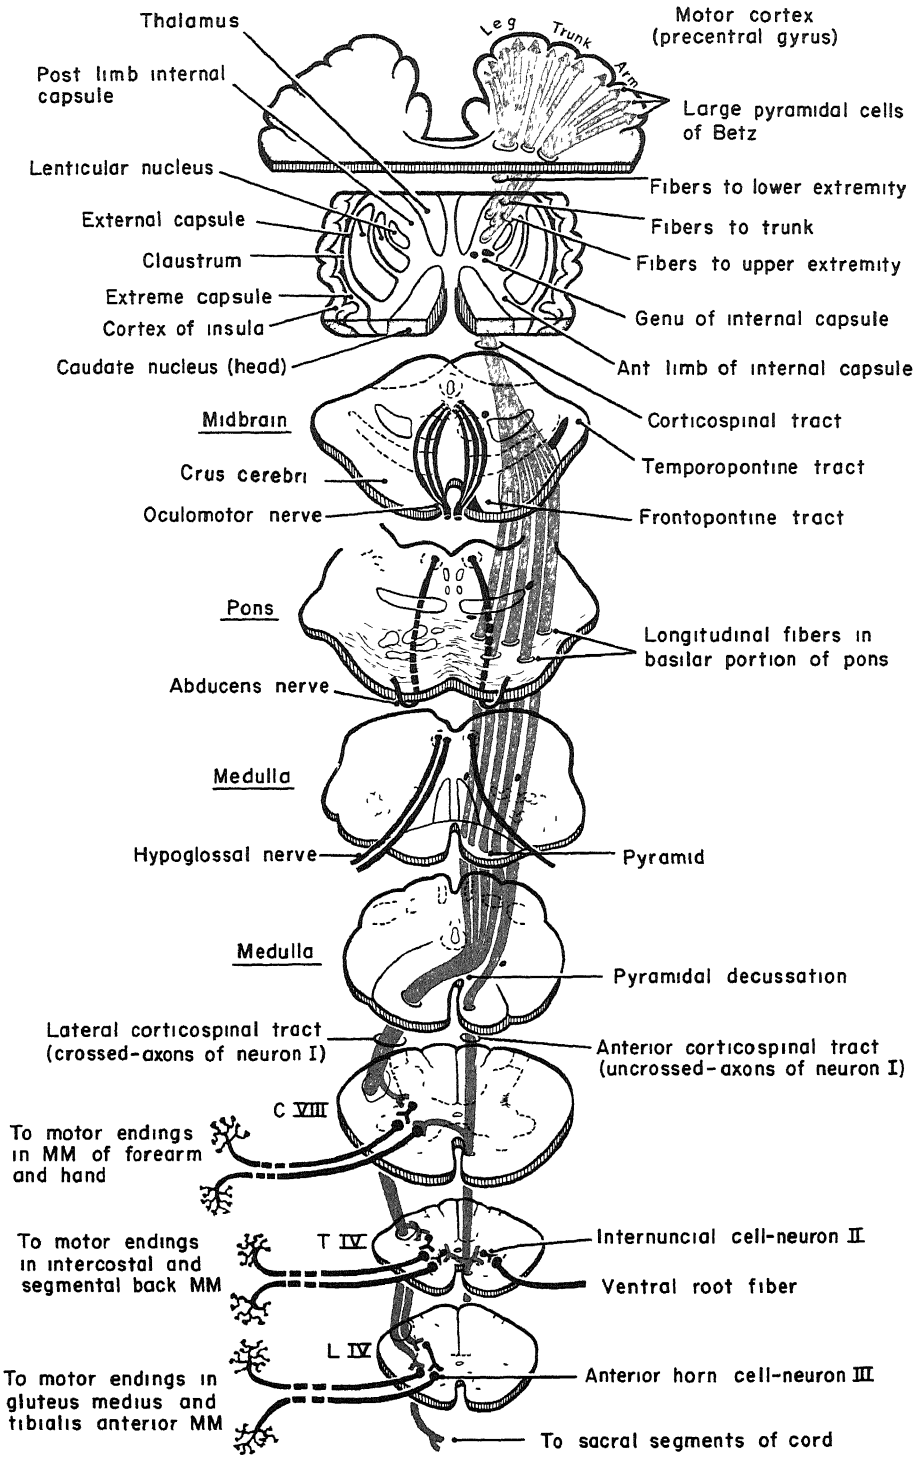

Fig 9 26 Diagram showing course of corticospinal fibers in lateral and anterior corticospinal tracts beginning in pyramidal cells of cortex running through internal capsule basis pedunculi pyramid and into spinal cord Location of corticobulbar tracts is shown also (*right side*) From Truex and Carpenter 1969

nated, although there is no evidence that they serve different functions or that there is any significant difference between them The *ventral vestibulospinal tract* arises predominantly from the spinal or inferior vestibular nucleus (in the cat) and descends in the forepart of the anterior funiculus of the spinal cord just lateral to the anterior corticospinal tract It is a downward extension of the medial longitudinal fasciculus (see below, p 9–30) The *lateral vestibulospinal tract* is a prominent descending pathway lying in the anterolateral part of the spinal cord It arises from the lateral vestibular or Deiter's nucleus and extends throughout the entire length of the spinal cord Most of its fibers are uncrossed although a few arise from the contralateral lateral vestibular nucleus The vestibulospinal fibers terminate either upon the anterior horn cells or upon small internuncial neurons which in turn form synapses with the motor cells of the anterior gray horns of the spinal cord

4) **Tectospinal Tracts** of each spinal half arise from the contralateral superior and inferior colliculi and descend at first as a single compact bundle through the reticular formation of the brainstem Upon reaching the cord the fibers are segregated into two fasciculi, a ventral and a dorsal, which descend in the ventral and lateral white columns, respectively The fibers synapse with the spinal motoneurons, either directly or through internuncial neurons, especially in the cervical region, wherein are situated the centers for the neck muscles Impulses from the retina are received by the superior colliculus which through such impulses, and its spinal connections serves as a center for the integration of visual impressions with body movement, especially of the head (*visuospinal reflexes*) This center is probably of less importance in man, with his highly developed visual cortex, than in animals Auditory reflexes may also be mediated by this tract and the inferior colliculus

5) **Rubrospinal Tract** arises from the large cells (nucleus magnocellularis) in the posterior part of the red nucleus The fibers immediately upon leaving the red nucleus cross to the opposite side (*Forel's decussation*) and descend through the reticular formation of the pons and medulla to enter the lateral funiculus of the cord ventral to the lateral corticospinal tract In carnivorous animals, e g , cat and dog, the rubrospinal tract is large and important In the primates, particularly in man, the rubrospinal tract is so small that its existence has been questioned, at any rate it has little if any known functional significance

6) **Olivospinal (Bulbospinal) Tract of Helweg** Its fibers are presumed to arise from cells in the neighborhood of the inferior olivary nucleus and descend in the ventral and lateral part of the lateral funiculus However, its existence has been seriously questioned It descends no farther than the cervical region The fibers synapse with motor neurons The functions of this tract are unknown It and the thalamo-olivary tract constitute a possible path whereby impulses from the thalamus may reach the spinal centers

7) **Reticulospinal Tracts** arise from cells scattered through the reticular formation of the brainstem They are two in number, one in which crossed fibers predominate descends in the anterior funiculus, the other composed mainly of uncrossed fibers, in the lateral funiculus They connect with the motor neurons in the anterior horns and probably with cells in the lateral horn Impulses conveyed over this complex pathway are concerned with the regulation of the reflux activity of the skeletal musculature, the control of the vegetative nervous system, adjustment of the threshold of peripheral end-organs such as the muscle spindles and of the sensory pathways

INTERSEGMENTAL TRACTS OF THE SPINAL CORD

There is in each funiculus of the cord lying close to the gray matter an intersegmental fasciculus or ground bundle These, as already mentioned, serve to link spinal segments of different levels Their fibers arise from cells in the gray matter and after an ascending or descending course of variable length end around cells of the same or of the opposite side at a higher or a lower level They include groups of fibers that have the following names *lateral intersegmental fasciculus* or *lateral ground bundle*, the *anterior intersegmental* or *sulcomarginal fasciculus, septomarginal fasciculus,* and the *posterior intersegmental fasciculus*

THE LONGITUDINAL FASCICULUS (OR BUNDLE)

The medial (posterior) longitudinal fasciculus (or bundle) is a tract of great physiolog-

ical importance and is present in all vertebrates It is composed of fibers which connect the 3rd, 4th, and 6th cranial nerves with one another and with the vestibular nuclei, and makes connections with the motoneurons of the cervical segments of the spinal cord The tract lies near the midline and extends from the cervical segments of the spinal cord, where it is continuous with the anterior intersegmental fasciculus (anterior ground bundle) to the floor of the 3rd ventricle In the medulla oblongata it lies immediately subjacent to the floor of the 4th ventricle, in the pons it courses through the formatio reticularis, and in the midbrain, lies in relation to the gray matter of the floor of the Sylvian (cerebral) aqueduct It also received fibers from the lateral lemniscus (auditory path) and from the superior colliculus, through which it is in communication with the optic pathway The essential function of the medial longitudinal bundle is the coordination of reflex movements of the ocular and neck muscles in response to labyrinthine, auditory, and visual stimuli

STRUCTURE OF THE BRAINSTEM

At lower levels of the medulla oblongata the homology of brainstem and spinal cord is obvious upon examination of cross sections As sections are cut progressively more rostrally, however, the brainstem exhibits more and more features that obscure its similarity to the cord, and one has to look closely to distinguish familiar landmarks As noted already, the principal ascending and descending pathways of the spinal cord pass through or on the brainstem, these provide useful clues as to the homology Other clues are found in the sensory and motor nuclei of the cranial nerves If the ventricular system of the brainstem is regarded as a modified, displaced, and flattened out continuation of the central canal of the spinal cord, the gray matter adjacent to the ventricles and aqueduct is then seen to be continuous with the gray columns of the spinal cord Instead of the dorsal-ventral relation found in the cord, however, the gray matter in the floor of the 4th ventricle possesses sensory elements laterally, autonomic motor components in an intermediate position, and motor cells medially This comes about because the dorsal tips of the gray columns have been, in effect, separated until the H of the spinal cord has become an open V (Fig 9 27) In many instances even this relationship is obscured by development of other structures, with a result that motor nuclei that theoretically should lie in or near the central gray substance near the midline are found in what appears to be a remote position, as in the case of certain nuclei of the facial nerve and of nerves IX, X, and XI, as described later

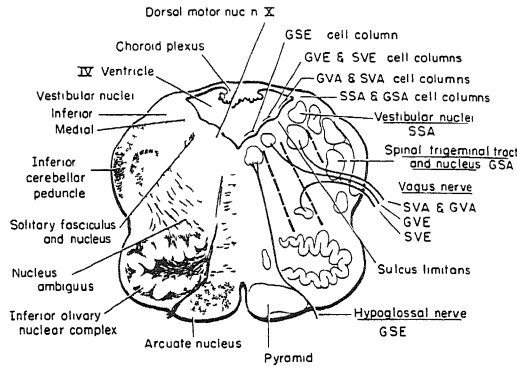

Fig 9 27 Schematic cross section of medulla oblongata to show appearance in stained section (*left*) and pattern of organization (*right*) Cell columns that contain nuclei of origin and termination of cranial nerves are abbreviated as follows *GSA* general somatic afferent *GSE* general somatic efferent *GVE* general visceral efferent *SVA* special visceral afferent *SVE* special visceral efferent From Truex and Carpenter 1969

Most of the apparent distortion of relationships in the brainstem, however, is associated with development of the cerebellum, its related structures, and its connections The principal functional relation of the cerebellum is with the cerebral cortex, their connection is achieved through fibers from the cerebrum that pass via the internal capsule and cerebral peduncles to nuclei imbedded in the pons, and thence by fibers of the pons that enter the cerebellum via the middle cerebellar peduncle For this system the main path of exit from the cerebellar nuclei is the brachium conjunctivum that runs in the rostral or superior cerebellar peduncle to the midbrain and thalamus It is the fact that both of these pathways contain a relatively large number of fibers, plus the cells located in the pons, that give the level of the metencephalon those characteristics that make it seem so different from the medulla below it and the mesencephalon above

That portion of the brainstem that seems to run continuously from spinal cord through medulla oblongata, metencephalon and mesencephalon (Fig 9 20) is known as the *teg-*

mentum (The name comes from a word that means "cover," and it is true that generally the tegmentum has a dorsad position, especially at the level of the pons In the mesencephalon, however, it in turn is covered by the corpora quadrigemina or *tectum*—a word that means "roof") The tegmentum contains the complex of cells and fibers known as the *reticular formation*, and certain of the nuclei of the cranial nerves In the medulla it includes all structures except the inferior cerebellar peduncles above, and the complex of olivary nuclei and the pyramids lying inferiorly The "olives," because of their conspicuous projection to the cerebellum, may be classified with other structures of the brainstem related to the development of the cerebellum

At the level of the metencephalon, a level usually but inexactly known as the pons, the tegmentum is hidden by the cerebellum above it and the pons below (Fig 9 20) At the level of the mesencephalon it is the corpora quadrigemina that lie in the superior position, with the substantia nigra and crus cerebri placed inferior to the tegmentum on each side The *red nuclei* are prominent collections of neurons located ventromedially in the tegmentum of the mesencephalon, surrounded by fibers of the brachium conjunctivum that seem to form a "capsule" for the nucleus

The Reticular Formation

The central portion of the tegmentum of the brainstem is occupied by a diffuse ill-defined mass of nerve cells and fibers known as the *reticular formation* It extends downward into the spinal cord and upward into the diencephalon It contains identifiable cell groups, however, as these have not been shown to have functional significance no cognizance of these nuclei will be taken here The reticular formation has been defined (see Segundo, 1956) as including all areas within the brainstem (excepting primary afferent pathways) which when stimulated will produce "arousal" (chap 8, p 9–150) This includes the bulbar reticular formation, the pontomesencephalic tegmentum, the hypothalamus, the subthalamus, and the ventromedial portion (including the intralaminar nuclei) and the reticular nucleus of the thalamus

The reticular formation receives afferent impulses from a great variety of sources These connections are by means of both direct afferent fibers and collaterals from the main afferent pathways to the cerebellum and thalamus Thus, the reticular formation receives afferent impulses from the optic, the olfactory, the auditory, and the gustatory systems as well as from the spinal and trigeminal pathways which bear impulses concerned with tactile, painful, thermal, and vibratory sensibilities and sensations from the muscles, joints, and tendons, and afferent impulses from the viscera and other internal structures of the body In addition afferent fibers converge on the reticular formation from the cerebellum, the basal ganglia, the thalamus, the rhinencephalon and the cerebral cortex Peculiarly, only certain specific portions of the cerebral neocortex seem to send afferent impulses to the reticular formation These are the orbital, oculomotor, sensorimotor and posterior parietal cortices, the superior temporal and cingular gyri, and the temporal pole In addition the activity of the reticular formation is influenced by certain hormonal and chemical changes (adrenalin, acetylcholine, carbon dioxide, etc) and by many drugs (barbiturates, anesthetics, tranquilizing compounds, etc)

In turn, efferent impulses from the reticular formation are conducted *i) cephalad* into the brain, particularly to all parts of the cerebral cortex, and *ii) caudad* into the spinal cord Because of the multisynaptic character of the pathways to and from the reticular formation and the small caliber of many of the fibers, reticulocortical conduction is much slower than in the primary sensory system The reticulospinal fibers run bilaterally in the lateral and ventral white columns of the spinal cord and transmission in this system is thought to be quite rapid

Cranial Nerves

Cranial nerves are numbered from above down, and will be considered in that order here even though this is contrary to the outline of the other material in this chapter (Figs 9 28 and 9 29) The nuclei of origin of the motor components of the cranial nerves will be classified as follows

1) Somatic efferent—to striated muscle via nerves III, IV, VI, and XII,

2) General visceral efferent—to smooth muscle and glands, via nerves III, VII, IX, and X,

3) Special visceral efferent—to striated

muscles derived from branchial arches, fibers run in nerves V, VII, IX, and X (and XI)

The nuclei of termination of afferent fibers, the nuclei that contain the cell bodies of second order sensory neurons, have the following classification

4) *Visceral afferent*—receiving taste and other fibers brought via nerves VII, IX, and X,

5) *General somatic afferent*—sensory nucleus and nucleus of the spinal tract of nerve V, a small contribution from nerve X,

6) *Special somatic afferent*—vestibular and cochlear nuclei of nerve VIII

Autonomic motor components of the cranial nerves belong to what is known as the parasympathetic portion of that system Their significance is discussed in the following chapter The general location of all of these nuclei is represented in relation to surface anatomy of the brainstem in Figure 9 30

OLFACTORY AND OPTIC NERVES (I AND II)

As noted earlier, these are not nerves like the other 10, in that they develop differently and have different types of connections The afferent fibers they contain do not arise from cells located in ganglia outside the central nervous system Rather, these two nerves should be regarded as fiber tracts of the brain Their function is considered in section 8 The olfactory nerve seems to contain only afferent fibers, whereas the optic nerve includes also fibers passing from the central nervous system to the retina

OCULOMOTOR, TROCHLEAR AND ABDUCENS NERVES (III IV AND VI)

The oculomotor nerve innervates all extrinsic muscles of the eye except the superior oblique muscle (innervated by trochlear nerve) and lateral rectus (by abducens nerve) These motor fibers arise from three separate somatic motor nuclei that belong to the column that includes also the motor nucleus of the hypoglossal nerve Autonomic fibers (preganglionic, see following chapter) to intrinsic muscles of the eye also run with the oculomotor nerve from their origin in the Edinger Westphal nucleus in the mesencephalon—the most rostral

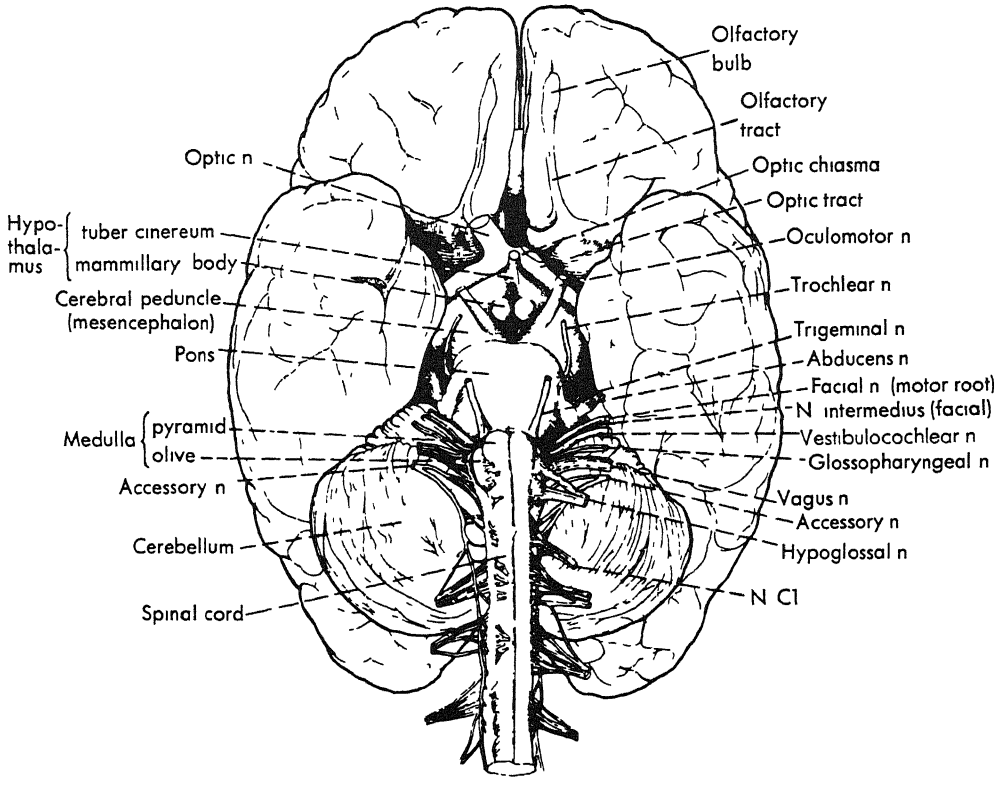

Fig 9 28 Inferior surface of human brain and upper part of the spinal cord From Henle 1868 reproduced from Hollinshead, 1967

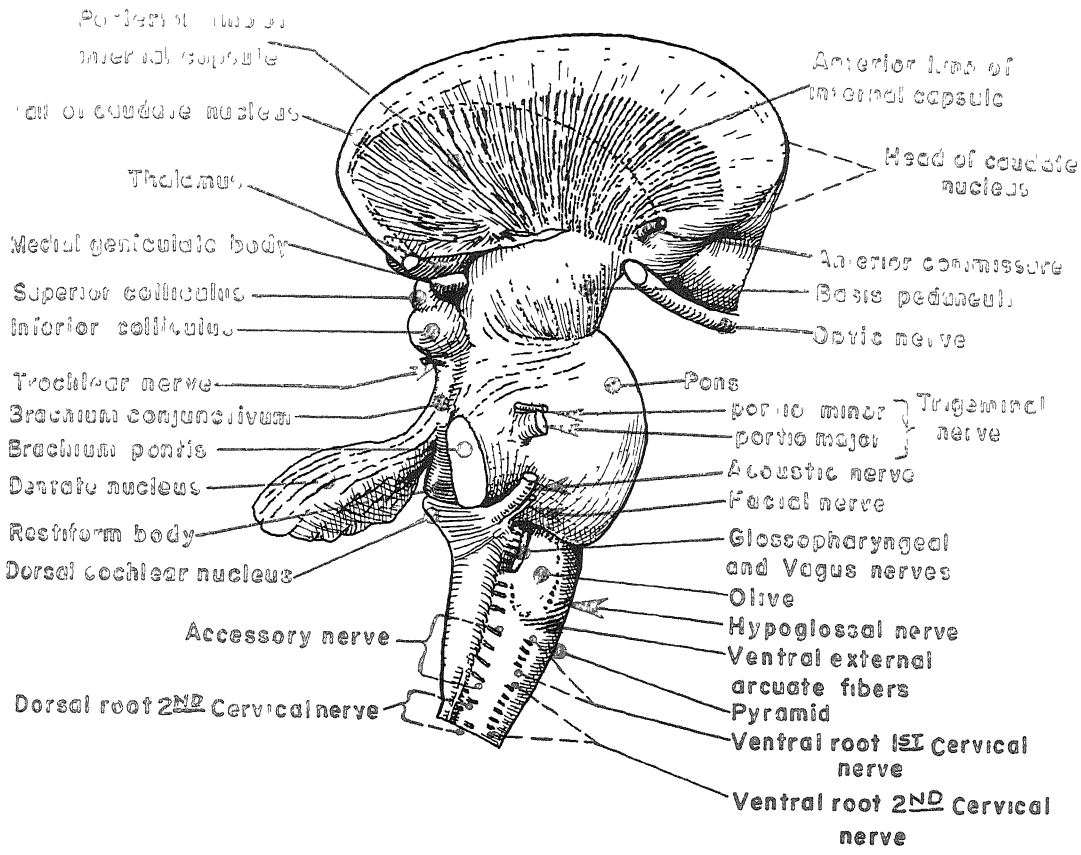

Fig 9 29 Lateral view of human brainstem Cranial nerves have been sectioned cerebellum has been removed by section of the three peduncles on each side all portions of the cerebrum lateral and superior to the internal capsule have been dissected away (Ranson and Clark 1959)

of the four general visceral motor nuclei Afferent fibers from extrinsic muscles of the eye are said to run in all three of these nerves, but their central connections are uncertain

The oculomotor nerves originate in the mesencephalon, and leave the brainstem inferiorly and medially on each side between the midline and the medial border of the cerebral peduncle Fibers of the trochlear nerve run dorsally around the central grey substance of the mesencephalon, cross in the region superior to and between the inferior colliculi, leave the brainstem, and then course around it en route to the orbit By its crossing this nerve becomes unique among nerves supplying extraocular muscles The abducens nerve makes its exit from the brainstem at the caudal border of the pons not far from the midline

TRIGEMINAL PATHWAYS

The trigeminal nerve appears on the lateral surface of the pons The nerve has three roots, *i*) a large *sensory*, *ii*) a *mesencephalic* that is also sensory, and *iii*) a small *motor* (Fig 9 31)

The fibers of the *sensory root* convey impulses from the anterior part of the scalp, from the skin of the forehead and face, with the exception of an area over the lower border of the mandible It also supplies the mucous membrane of the mouth, anterior two-thirds of tongue and nose, the cornea and conjuctivae, and part of the intracranial dura mater This root arises from the cells of the gasserian (semilunar) ganglion, which corresponds to a spinal posterior root ganglion The processes of the ganglion cells divide into peripheral and central branches The former enter into the composition of the peripheral divisions (ophthalmic, maxillary, and mandibular) of the nerve, the central branches (which constitute the sensory root of the nerve) enter the pons in close association with the fibers of the motor root and divide into an ascending and a descending group in a manner homologous with a spinal root fiber The *ascending fibers* convey impulses of light touch, tactile discrimination and localization, and of the sense of position and passive movement They end in a

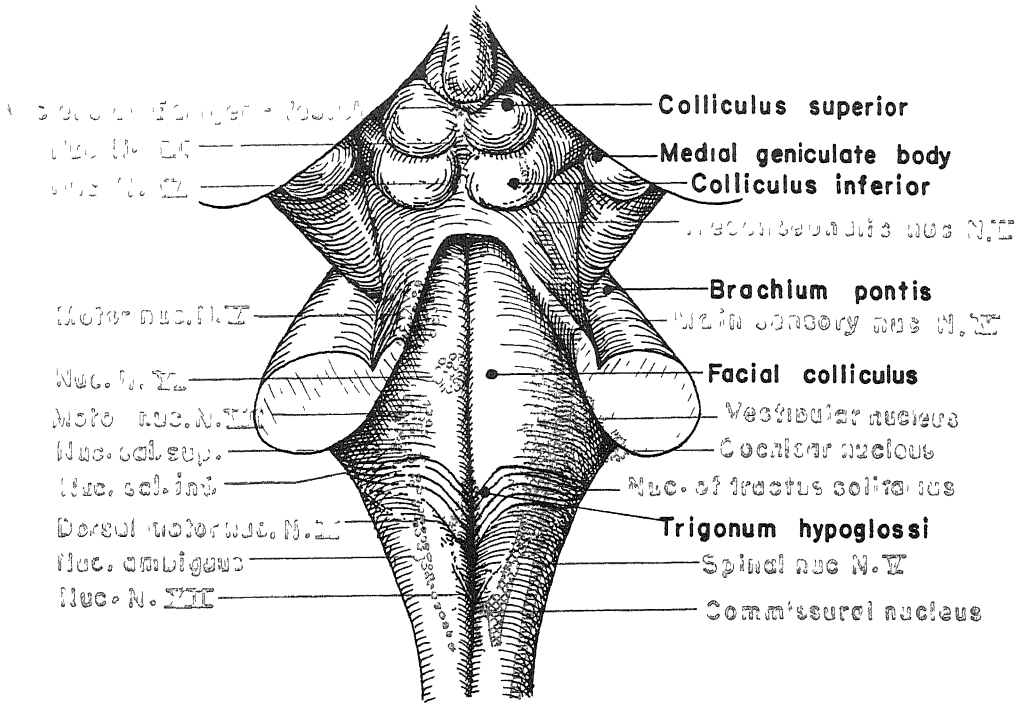

Fig 9 30 Dorsal view of human brainstem with positions of cranial nerve nuclei projected upon the surface Motor nuclei are on the left sensory nuclei on the right Herrick from Ranson and Clark 1959

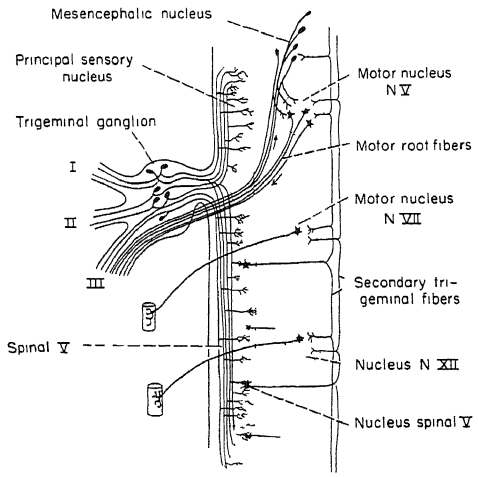

Fig 9 31 Diagram of peripheral and central distribution of sensory and motor fibers in trigeminal nerve I ophthalmic II, maxillary, and III mandibular divisions From Truex and Carpenter 1969

nucleus (*main* or *upper sensory nucleus of the trigeminal nerve*) situated in the pons, deep and lateral to the motor nucleus The axons of cells in this nucleus ascend with those from the spinal nucleus of the trigeminal nerve (see below) to form the *trigeminal lemniscus* The *descending fibers* constitute the *bulbospinal tract of the trigeminal nerve* They subserve sensations of pain and temperature over the entire trigeminal area They descend through the pons and medulla oblongata and may be traced as far as the 2nd cervical segment This tract dwindles gradually in its descent, its fibers terminating around cells in the substantia gelatinosa of Rolando which in this situation is referred to as the *spinal nucleus of the trigeminal nerve* From the spinal nucleus the axons of secondary neurons swing downward in the spinal tract of the trigeminal nerve as far as the upper cervical spinal cord They then cross the midline and turn upward In the upper part of the medulla oblongata they join fibers arising from the upper sensory nucleus to form the *trigeminal lemniscus* (or fillet) The trigeminal lemniscus lies in close association with the medial and the spinal lemnisci (spinothalamic tracts) (p 9–25), its fibers terminate in the posteroventral nucleus of the thalamus

The main sensory nucleus of the trigeminal corresponds to the nuclei of the posterior columns of the spinal cord (nuclei gracilis and cuneatus) and like the latter sends fibers to the cerebellum through the inferior cerebellar peduncle The spinal tract of the trigeminal

nerve may be looked upon as corresponding to the tract of Lissauer (p 9–24), and the spinal nucleus as an extension upwards of the substantia gelantinosa of Rolando

A number of reflexes are mediated through the afferent fibers of the trigeminal nerve, e g , corneal, winking, sneezing, and oculocardiac

The *mesencephalic root* consists of a small bundle of afferent fibers which run in company with the fibers of the motor root Entering the pons they ascend to the *mesencephalic nucleus* of the trigeminal, an elongated collection of first order sensory nerve cells extending from the level of the motor nucleus to the upper region of the midbrain The nucleus is looked upon as a group of cells homologous with the gasserian (semilunar) ganglion and the posterior root ganglia of the spinal nerves, but which has migrated or been "drawn" into the brainstem at an early period of phylogenetic development It is believed to receive proprioceptive impulses from the muscles of mastication and possibly from the ocular muscles

The *motor root* fibers arise from a nucleus in the upper part of the pons underlying the lateral part of the floor of the 4th ventricle The nucleus receives fibers from the corticobulbar tract of the opposite side and also probably from the same side The motor root after its emergence from the brainstem, travels peripherally with the sensory root and, passing deep to the gasserian ganglion, joins the mandibular (3rd) division of the trigeminal nerve to supply the muscles of mastication (temporal, masseter and pterygoids)

Lesions Involving the Trigeminal Pathways Either the peripheral portions or the central connections of the nerve may be the seat of disease A lesion of the nerve peripheral to the ganglion is more likely to involve only one of its three divisions Pain, or loss of sensibility over the distribution of the divison affected, may result If the gasserian ganglion is involved the disturbance of sensation usually involves the area of distribution of more than one division, often of the entire nerve If as a result the eye is rendered anesthetic the patient may develop an ulceration of the cornea and an inflammation of the cornea and conjunctiva This has often been referred to as a neuroparalytic keratitis and has been attributed to the loss of some obscure trophic influence of the nerve Actually it results from the fact that the eye is anesthetic and can be injured easily by a foreign body or by scratching without any discomfort to the patient The eye is then likely to be neglected by the patient because it is not painful As a result he may lose his sight or even his eye

Herpetic eruptions may result from the involvement of the gasserian ganglion Spontaneous herpes zoster usually involves the area of distribution of the ophthalmic division and is often serious because the lesions on the cornea may lead to corneal opacity and loss of vision Such herpes is also commonly followed by a very distressing postherpetic neuralgia which is very difficult to treat satisfactorily

The trigeminal nerve, or one of its divisions, is sometimes the seat of a severe and intractable type of pain which recurs in paroxysms (*trigeminal neuralgia, tic douloreux*) The cause of the affection is unknown

Paralysis of the muscles of mastication with reduction in the strength of the bite on the affected side and deviation of the mandible toward the paralyzed side when it is opened occurs when the motor division is involved

THE FACIAL NERVE

The facial nerve consists of a large *motor* and a small *sensory* portion The two portions or roots appear at the lower border of the pons and enter the internal auditory meatus in company with the auditory nerve (Fig 9 32)

The *sensory* root of the facial, which is also known as the *nervus intermedius of Wrisberg*, contains not only afferent fibers but secretory and vasodilator (parasympathetic) fibers as well

The *sensory fibers* arise from the cells of the geniculate ganglion The peripheral processes of these cells are distributed through the chorda tympani branch of the facial nerve to the taste buds and mucous membrane of the anterior two-thirds of the tongue, and through the nerve to the pterygoid canal (formed by the union of the greater superficial petrosal and the deep petrosal nerves), and the sphenopalatine ganglion to the lacrimal gland and the mucosa of the soft palate and posterior part of the nose The chorda tympani branch joins the trunk of the lingual nerve through which it is conveyed to the floor of the mouth The central processes of the ganglion cells end in the *sensory nucleus* situated in the upper part of the *tractus solitarius* Fibers arise from the

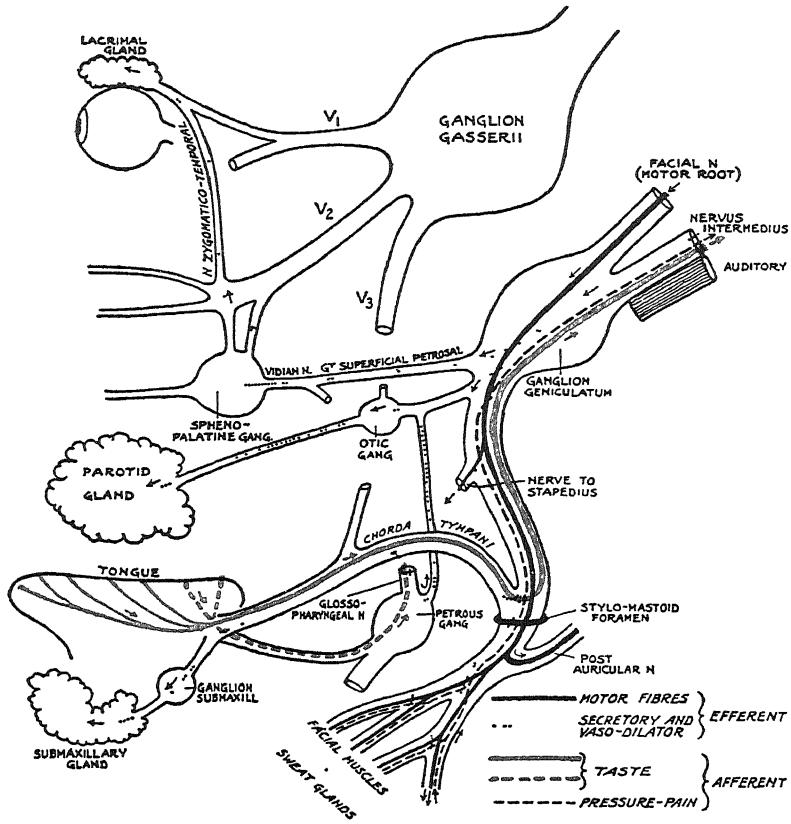

Fig 9 32 Components and distribution of the facial nerve (Treux and Carpenter 1969)

latter and ascend in the medial fillet of the opposite side to reach the thalamus

The *parasympathetic fibers* arise from the *superior salivatory nucleus* which lies in close relation to the motor nucleus of the facial After leaving the brainstem in the sensory root the parasympathetic secretory and vasodilator fibers pass via the *great superficial petrosal* nerve and *nerve to pterygoid canal* (formed by the union of the great superficial and deep petrosal nerves) to the *sphenopalatine ganglion* from where the postganglionic fibers arise to pass to the lacrymal gland, and to the vessels and glands of the palate and posterior part of the nose The secretory and vasodilator fibers to the submaxillary and sublingual glands leave the facial with the taste fibers in the chorda tympani branch

The *motor part* of the facial is conveyed through the facial canal of the temporal bone to the stylomastoid foramen After its emergence from the latter it is distributed to muscles of the face, auricle, and forehead. The motor fibers arise from a nucleus in the lower part of the pons and pass backwards to the lower end of the nucleus of the abducent nerve Then ascending to the upper end of the latter they bend and sweep downwards and forward to where they leave the brain As the facial fibers take this arched course to the point of their emergence from the brainstem, they, together with the abducent nucleus, form a prominence in the floor of the 4th ventricle, known as the *facial colliculus*

Facial Paralysis. The effects of interruption of the facial pathway vary in certain important features according to the level at which the injury occurs In the paralysis resulting from division to the trunk of the facial nerve all the muscles of the affected side of the face are completely paralyzed The subject is unable to close the eye owing to paralysis of the orbicularis oculi, or to frown, the eyebrow droops The mouth is drawn over to the sound side by the unparalyzed muscles and the muscles of the affected side do not take part in the facial expression of emotional states, e g, laughing or crying

Facial paralysis may result from a lesion involving

1) The motor nucleus or the intrapontine course of the motor fibers (tumors, hemorrhage, etc)

2) The nerve as it crosses the posterior fossa of the skull to reach the internal auditory meatus, as in fractures of the skull or tumors in this location, the sensory portion and the auditory nerve are commonly involved as well, with loss of the sensation of taste over the anterior two-thirds of the tongue, and deafness on the affected side

3) The nerve in its course through the temporal bone as in fracture of the skull or in otitis media, inflammation of the nerve within the facial canal (aqueduct of Fallopius)—*Bell's palsy*—may occur

4) The nerve after its emergence from the stylomastoid foramen, as it lies behind the angle of the jaw, inflammation, parotid tumors, or accidental injuries may implicate the nerve in this situation

VESTIBULOCOCHLEAR NERVE

The 8th cranial nerve is a true nerve, different from the olfactory and optic nerves even though in function the three nerves seem comparable because they innervate organs of special sensation One of the major parts of this nerve contains sensory fibers from neurons located in the vestibular ganglion, with peripheral processes innervating semicircular canals, utricle, and saccule The other major part contains sensory fibers from cells of the spiral ganglion of the cochlea, their short, peripheral processes supply the hair cells of the organ of Corti A third and minor part of the nerve consists of efferent fibers to the organ of Corti, where they apparently modulate the sensitivity of the hair cells (Galambos, 1956) This group of fibers is known as the *efferent cochlear bundle*

More complete information about the functions of this nerve is given in the section on "Sensory Systems," section 8, chapter 2

GLOSSOPHARYNGEAL NERVE

The glossopharyngeal nerve contains motor, secretory, vasodilator, and sensory fibers The nerve emerges from the side of the upper part of the medulla oblongata in the groove between the olive and the restiform body Its special visceral motor fibers arise from the upper part of the *nucleus ambiguus* situated in the reticular formation of the medulla oblongata They are distributed almost entirely to the stylopharyngeus muscle, a few terminate in the circular and longitudinal muscle of the upper part of the pharynx However, division of the glossopharyngeal nerve, which is done for glossopharyngeal neuralgia, produces no motor disability so far as the patient is concerned Secretory and vasodilator fibers are the axons of cells lying in the *inferior salivatory* nucleus, which lie below the superior nucleus of the same name Via the tympanic branch of the nerve they supply the tympanic plexus, the small superficial petrosal nerve, the otic ganglion, and thence the parotid gland The sensory fibers arise from cells in the superior (jugular) and inferior (petrous) ganglia of the glossopharyngeal nerve The peripheral processes of the cells of the latter ganglion supply the taste buds of the posterior third of the tongue Those from cells of the *superior* ganglion mediate *ordinary sensations* (touch, thermal, etc), from this part of the tongue and the mucosa of the pharynx and posterior part of the mouth, the central processes (superior ganglion) terminate in the *dorsal nucleus* of the vagus and (inferior ganglion) in the lower part of the *tractus solitarius* Fibers (secondary neurons) pass from the latter nucleus and, crossing to the medial fillet of the opposite side, ascend to the thalamus, from where axons of tertiary neurons pass to the cortical area for taste

The carotid sinus nerve is another important afferent branch of the glossopharyngeal nerve It is concerned with the conduction of impulses from the carotid body and the carotid sinus to the medulla oblongata These impulses and their frequency are determined by chemical changes in the blood which are detected by the carotid body and by changes in the blood pressure which are detected by the carotid sinus These afferent impulses are concerned in reflex activities which take part in controlling the pulse rate, the respiratory rate, and the blood pressure

VAGUS NERVE

The vagus nerve contains motor, secretory, vasodilator, and sensory fibers The secretory and vasodilator fibers and the fibers to the involuntary muscle of the bronchi, heart, esophagus, stomach, small intestine, gallblad-

der, etc (parasympathetic fibers) arise from cells in the *dorsal nucleus of the vagus* (principal autonomic nucleus) This gray mass is the principal autonomic motor mechanism in the brainstem It belongs to the *general* visceral efferent group of nuclei, and extends upwards from the lower closed part of the medulla oblongata to beneath the floor of the 4th ventricle at the level of the striae medullares The *special* visceral motor fibers arise in close relationship with the motor fibers of the glossopharyngeal nerve, namely, from the cells of the *nucleus ambiguus* lying below the glossopharyngeal neurons They supply (through the superior laryngeal branch) the cricothyroid and arytenoid muscles of the larynx, and the inferior constrictor of the pharynx The pharyngeal and recurrent laryngeal branches of the vagus also convey motor fibers many of which are derived from the bulbar nucleus of the accessory nerve (see below) to the pharyngeal muscles (with the exception of the stylopharyngeus), and to the muscles of the soft palate (except the tensor palati) and larynx (except the cricothyroid) The cell bodies of the *sensory fibers* lie in the inferior ganglion of the vagus (ganglion nodosum) The peripheral processes of these cells convey impulses from the lungs, heart, larynx, pharynx, esophagus, stomach, small intestine, and gallbladder They also, through the anterior laryngeal branch, innervate the taste buds of the epiglottis and valleculae (the depressions lying at the sides of the fold running from the epiglottis to the base of the tongue) The taste fibers end centrally by synapsing with cells in the *gustatory nucleus* lying in the upper and medial part of the *tractus solitarius* These impulses are relayed upwards along the same paths as those conveying other taste impulses Afferent vagal fibers from visceral structures terminate in the dorsal nucleus This latter is, therefore, both motor and sensory in function and constitutes an important visceral reflex center It contains the cardioinhibitory and vomiting centers

Vagal afferent filaments travelling in Arnold's nerve mediate the general sensations of the skin lining the external auditory meatus and a small area behind the auricle Irritation of these fibers may cause reflex coughing These sensory fibers have their cell stations in the jugular ganglion

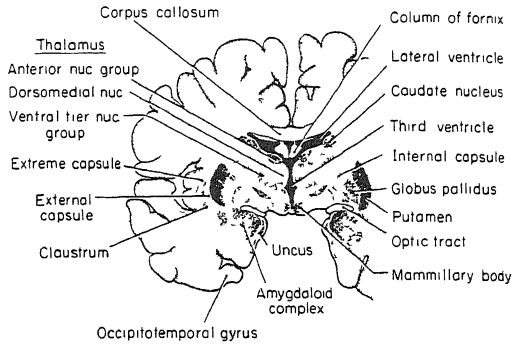

Fig 9 33 Cross section of cerebrum through thalamus and basal ganglia to show relations of these structures corpus callosum ventricular system and other portions of the brain Mammillary bodies are in caudal part of hypothalamus From Truex and Carpenter 1969

SPINAL ACCESSORY NERVE

The spinal accessory nerve is entirely motor and is made up of a bulbar and a spinal root The *bulbar* or special visceral motor root arises from the lower (caudal) end of the nucleus ambiguus from cells situated below those which give origin to the motor fibers of the vagus The bulbar fibers join the vagus within and below the jugular foramen and are distributed, as already mentioned, in the pharyngeal and recurrent branches of the latter nerve, these fibers of the spinal accessory nerve innervate the muscles of the larynx, with the exception of the cricothyroid, the muscles of the pharynx and those of the soft palate, with the exception of the tensor palati (which is supplied by the 5th cranial nerve) The *spinal* root is somatic motor and is composed of the axons of a group of cells in the anterior gray column of the spinal cord extending from the 1st to the 4th or 5th cervical segment inclusive These fibers supply the sternocleidomastoid and trapezius muscles The spinal part of the nerve exchanges fibers with the bulbar part in the jugular foramen

HYPOGLOSSAL NERVE

The hypoglossal nerve is also said to be purely motor, although it may carry proprioceptive fibers from the tongue. Its fibers are derived from a somatic motor nucleus situated near the midline in the floor of the posterior part of the 4th ventricle and medial to the nucleus ambiguus It supplies the thyrohyoid, styloglossus, hyoglossus and genioglossus muscles, and the intrinsic muscles of the tongue

Thalamus

This large gray mass is related medially to the 3rd ventricle which lies between the thalami of the two sides The thalami are joined across the midline by an isthmus, the *massa intermedia* (Fig 9 20) The posterior limb of the internal capsule lies upon the outer side of the thalamus and separates it from the lentiform nucleus Above the thalamus is the lateral ventricle, a part of whose floor it forms (Fig 9 33) In front is the head of the caudate nucleus, the arched *body* of the latter is related to the upper part of the lateral surface of the thalamus Below the thalamus are the corpus of Luys (subthalamic nucleus) and the forepart of the red nucleus

NUCLEAR GROUPS

There are five main nuclear masses in the thalamus

A) Nuclei of the Medial Mass. *1) Anterior Nuclei* These form a mass which bulges into the lateral ventricle (Fig 9 34) They receive fibers from the mammillary bodies (tract of Vicq d'Azyr), and they send fibers to the paracentral lobule and the posterior part of the cingular gyrus on the medial aspect of hemisphere *2) Dorsomedial Nuclei* These consist of a dorsolateral group of small cells, and a medial collection of large cells The former project to prefrontal areas of the cerebral cortex The large-celled portion is connected by both afferent and efferent fibers with the hypothalamus, it also projects to the corpus striatum, and has rich afferent connections with other thalamic nuclei The dorsomedial nuclei are said to serve as an association center for visceral and crude somatic sensations

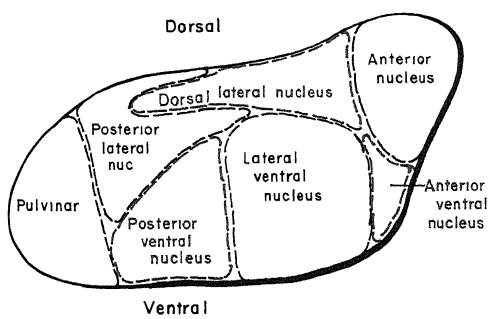

Fig 9 34 Drawing that shows relations of main divisions of the thalamic nuclei

B) Nuclei of the Lateral Mass *1) Ventral Group* This consists of *a) Anterior ventral nucleus* (also known as the ventral anterior nucleus) which receives fibers from the globus pallidus and projects to different parts of the corpus striatum, but not to the cerebral cortex This nucleus occupies the most anterior (rostral) extremity of the lateral mass *b) Lateral ventral nucleus* (the ventral lateral nucleus) The fibers entering the anterolateral part of this nucleus arises in the globus pallidus, whereas those ending in the posterior and medial part of this nucleus are derived mainly from the dentate nucleus of the contralateral half of the cerebellum (via the dentatothalamic and the dentatorubrothalamic tracts) Its efferent fibers pass to area 4, and in much smaller numbers to area 6 of the precentral motor cortex Thus, a pathway is established through which voluntary movements can be brought under the influence of the basal ganglia and the cerebellum *c)* The *posterior ventral nucleus* (ventral posterior nucleus) is the main subcortical center for sensory impulses ascending in the trigeminal, medial and spinal lemnisci (proprioceptive from muscles and joints, light touch, discrimination of two points, pain, heat, and cold) It projects to the postcentral gyrus (somesthetic area), areas 1, 3, 2, 5, and 7 This nucleus also sends fibers to the hypothalamus and corpus striatum The posterior ventral nucleus is composed of two subsidiary parts *i)* the *posteromedial nucleus*, which receives the trigeminal fibers, and *ii)* the *posterolateral nucleus* which is the thalamic station for the medial and spinal lemnisci Within this nucleus there is a definite somatotopic organization, the leg is represented most laterally, the face most medially, and the trunk and upper extremity in between

2) Dorsal Group This is also called the *lateral nucleus of the thalamus* It is subdivided into an anterior and a posterior portion, designated, respectively, the *dorsolateral* and *posterolateral nuclei*

C) The Nuclei of the Midline are, as mentioned above, situated in the massa intermedia, and in the adjacent part of the medial mass forming the upper part of the wall of the 3rd ventricle They are phylogenetically the oldest of the thalamic nuclei and are a center for the most primitive forms of sensation, e g , from the viscera and other structures oc-

cupying the axial regions of the body The midline nuclei are connected by many fine myelinated fibers with other subcortical centers, namely, the hypothalamus and midbrain nuclei They also receive fibers from the corpus striatum These nuclei have many intrathalamic connections but few if any fibers pass to the cerebral cortex, corpus of Luys (subthalamic nucleus), and the forepart of the red nucleus

D) The Intralaminar Nuclei are scattered groups of cells within the internal medullary lamina The connections of these nuclei are imperfectly known, but they are thought to receive both trigeminal fibers and fibers of the medial lemniscus, they are believed to belong to the reticular activating system They project to the globus pallidus and have many connections with neighboring thalamic nuclei A well-defined nucleus in the middle of the thalamus, and usually classed with this group is known as the *central* or *centromedian nucleus* It is especially well marked in primates, and is possibly an intrathalamic integrating center

E) The Pulvinar is the expanded continuation posteriorly of the lateral nuclear mass It overhangs the superior colliculus It projects to the cortex, its inferior part to an area comprising part of the temporal lobe, and the anterior part of the occipital lobe The rest of the pulvinar projects mainly to the parietal and temporal lobes

FUNCTIONS OF THE THALMUS

Known functions of the thalamus can be summarized under three headings, listed here in order of the amount of information available about each one

1) Sensation The thalamus and metathalamus contain the highest subcortical stages of projection of all sensory pathways of the body, with the exception of those serving olfaction Pathways from the body and head project via medial, spinal, and trigeminal lemnisci to the posterior ventral nucleus, whereas those from the eyes project to the lateral, and those for audition to the medial, geniculate body The principal pathways to the cortex, in turn, arise from these same diencephalic mechanisms A fuller account is given in section 8

2) Arousal Nuclei of the midline and the intralaminar nuclei are believed to constitute an essential part of the ascending activating system or the arousal mechanism, that originates in the reticular formation of the tegmentum and projects to cerebral cortex to keep it in a waking stage The cortical projections of these nuclei, however, are not obvious This function is discussed also in connection with the phenomenon of sleep, p 9-151

3) Association or *modulation* Practically all thalamic nuclei receive fibers from certain related parts of the cerebral cortex The discovery of these pathways that run from the cortex into the thalamus, in addition to the thalamic-cortical projections of the main sensory paths, has suggested that the cortex and thalamus somehow function together rather than independently as separable levels or stages in control or sensory systems When the word, "association," is used to describe this function, it does not have a technical meaning, but is used to describe what is not clearly motor or sensory In spite of the mysterious nature of these interrelations, the pathways are there, and they may be taken as evidence that there are, indeed, thalamic-cortical-thalamic interactions, or possibly those that are corticothalamic-cortical, and that perhaps modulate the activity of both the diencephalic and telencephalic levels of function This possibility is mentioned again later with reference to functions of the cerebral cortex, p 9-118

Hypothalamus

The hypothalamus is the anterior or ventral part of the diencephalon It is composed of neurons and their processes, both myelinated and unmyelinated, that lie in the walls and floor of the 3rd ventricle, and that form the infundibulum and pars nervosa of the pituitary gland It is bounded laterally by a plane marking the medial tips of the internal capsule, superiorly its boundary is the so-called hypothalamic sulcus in the wall of the 3rd ventricle Rostrally it ends at the plane joining the anterior commissure and optic chiasma, but histologically there is no difference between the tissue that lies above this boundary and belongs to the telencephalon, and that below the boundary in the diencephalon Consequently, the preoptic region of the telencephalon is often treated as a part of hypothalamic mechanisms In a similar fashion the caudal boundary of the hypothalamus is not sharply demarcated, it passes gradually into the tegmentum of the mesencephalon As noted ear-

her, the bulbar facilitatory mechanism extends through this region of transition and into the lateral hypothalamus

LEVELS IDENTIFIED BY EXTERNAL LANDMARKS

On the inferior surface of the hypothalamus there is a series of characteristic structures that serve as landmarks for identification of sections through this part of the brain (Fig 9 20) as follows

1) Rostrally is located the *optic chiasma*, the region over it is known as the suprachiasmatic level of the hypothalamus

2) Behind the chiasma is a prominence called the *tuber cinereum* ("grey swelling") created by the presence of the ventromedial nuclei near the base of the hypothalamus Between them arises the pituitary stalk (infundibulum) containing fibers joining nuclei of the hypothalamus and the posterior lobe (pars nervosa) of the pituitary gland The inferior surface of the stalk where it joins the hypothalamus proper, and where the vestigial cavity of the stalk opens into the 3rd ventricle, is known as the *median eminence*, it lies in the floor of the 3rd ventricle This part of the hypothalamus is known as the tuberal level

3) Behind the tuber on each side there is a prominent collection of nuclei known as the mammillary bodies because of their external form Above them the portion of the hypothalamus that is continuous through all of its levels undergoes its unmarked transition to become the mesencephalic tegmentum At this level the hypothalamus, proper, lies dorsad to the mammillary bodies much as the mesencephalic tegmentum lies above the bases pedunculorum

MICROSCOPIC ANATOMY

The hypothalamus also can be divided longitudinally into a medial portion containing neurons and unmyelinated fibers, continuous caudally with the central grey substance of the mesencephalon, and a lateral portion containing cells and both myelinated and unmyelinated fibers, continuous caudally with the reticular substance of the brainstem Rostrally the lateral region passes without obvious change into a subcortical reticular substance of the orbital portion of the frontal lobes

Two of the principal relations of the hypothalamus are with the pituitary gland (Fig 9 35) First, unmyelinated fibers from the supraoptic and paraventricular nuclei, as well as from other neurons, are gathered through the median eminence into the infundibulum and thence run to terminations in the posterior lobe (Some end in median eminence and the stalk) These are neurosecretory fibers, releasing antidiuretic and oxytocic hormones into the blood perfusing the posterior lobe (sect 7, chap 3) Second, other neurosecretory fibers not specifically identified as yet end in the ventral portions of the hypothalamus including the median eminence, where hormones known as "releasing factors" are secreted into capillaries perfusing this portion of the brain The blood from these capillaries is gathered into a second set of vessels, the hypophysial portal system, that runs along the stalk to the anterior lobe (pars distalis) of the gland The presence of these releasing factors in the blood perfusing the pars distalis controls the secretory functions of this important endocrine organ (sec 7, chap 2)

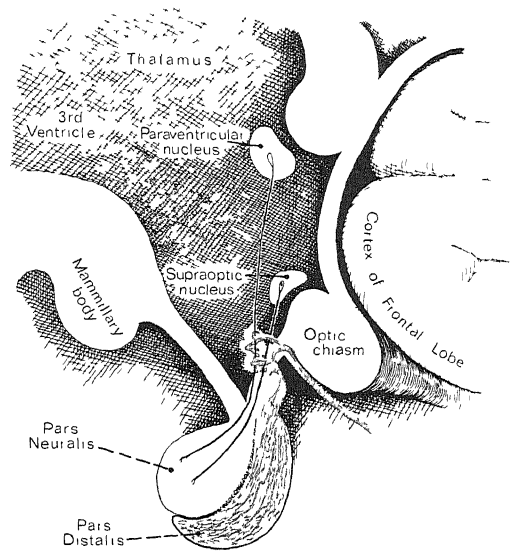

Fig 9 35 Drawing to show neural connections between hypothalamus and pars neuralis with vascular link between ventral hypothalamus and pars distalis the hypophysial portal system

Nuclei. Cells of the preoptic region are sometimes called the *preoptic* nucleus, they lie in the region of junction of telencephalon and diencephalon, and their level of origin is uncertain More caudally are found the large, deeply staining cells of the *paraventricular* and *supraoptic* nuclei The supraoptic nucleus is a

column of cells that lies over the lateral part of the chiasm and then extends back over the hypothalamic portion of the optic tract The paraventricular nucleus has the shape of a disc lying in the wall of the 3rd ventricle These nuclei are conspicuous in any stained cross-section through the rostral hypothalamus They have a rich blood supply, and they send their processes into the neural lobe by way of the median eminence and stalk, as just described In the tuberal region of the hypothalamus are two identified cell groups, the *dorsomedial* nucleus and the *ventromedial* nucleus Connections and function of both are obscure, it is known, however, that lesions in or inferior lateral to the ventromedial nuclei lead to hyperphagia and obesity In the caudal portion of the hypothalamus above the *mammillary* nuclei is the *posterior* nucleus on each side, its connections are uncertain The mammillary nuclei are of unknown function, in spite of the fact that they can be observed so easily and their connections are relatively well known (see next paragraph)

Fiber Connections. The hypothalamus receives fibers from the globus pallidus (pallidohypothalamic tract), from the amygdaloid nucleus, and through the *medial forebrain bundle*, from the olfactory lobe and the parolfactory area The medial forebrain bundle sweeps through the hypothalamus and in its course gives off fibers to several of the hypothalamic nuclei The hypothalamus, especially the supraoptic and paraventricular nuclei, also receives fibers from prefrontal areas and the precentral motor area (6) of the cerebral cortex (chap 6) both directly and indirectly through the thalamus There are probably afferent fibers from the spinal cord, doubtless similar to the direct and collateral ascending afferents which go to the bulbar part of the reticular formation It also projects through the anterior and the dorsomedial nuclei of the thalamus to prefrontal areas The most prominent tract from the hypothalamus to the thalamus is the mammillo-thalamic tract (of Vicq d'Azyr) from the medial mammillary nucleus to the anterior nuclei of the thalamus Other efferent tracts pass backwards in close relation to the ependyma of the 3rd ventricle, and descend in the gray substance of the midbrain (surrounding the cerebral aqueduct), pons, medulla (beneath the floor of the 4th ventricle), and spinal cord

The various hypothalamic nuclei are in communication with one another through fiber tracts, the best known of these is the paraventricular-supraoptic tract, but others undoubtedly exist

General Structure and Divisions

The cerebellum ("small brain") is the dorsal portion of the metencephalon, and lies in the posterior fossa of the cranium superior to the tegmentum of the mesencephalon, metencephalon, and medulla oblongata It is connected with the brainstem by the superior, middle, and inferior peduncles (Fig 9 36) at these same three levels, respectively, although the fact that the three peduncles seem to be gathered as a stalk gives the impression that its connections are mainly with the metencephalon lateral to and above the pontile tegmentum The cerebellar surface has a characteristic patterning, being divided by parallel and curved furrows into numerous laminae or folia ("leaves") Within each folium the arrangement of neurons of the cerebellar cortex is a significant feature of cerebellar organization, and will be described in some detail later The total area of the cerebellar cortex as it is folded in and out to form the folia is said to be about 100,000 mm ^{2}, a figure that is less than half the area of the cerebral cortex

When it is examined externally the cerebellum seems to have subdivisions, which have been given anatomical names (Fig 9 37) The physiological significance of many of these di-

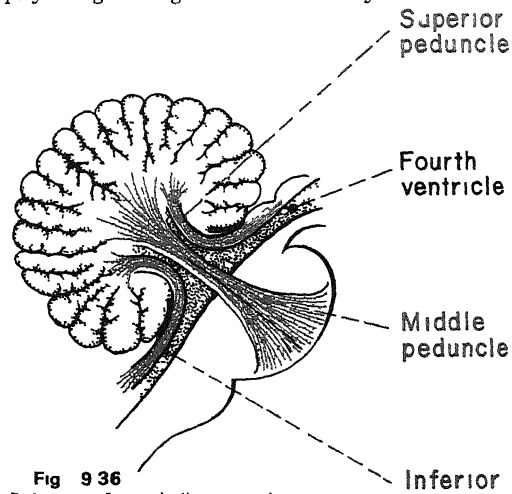

Fig 9 36

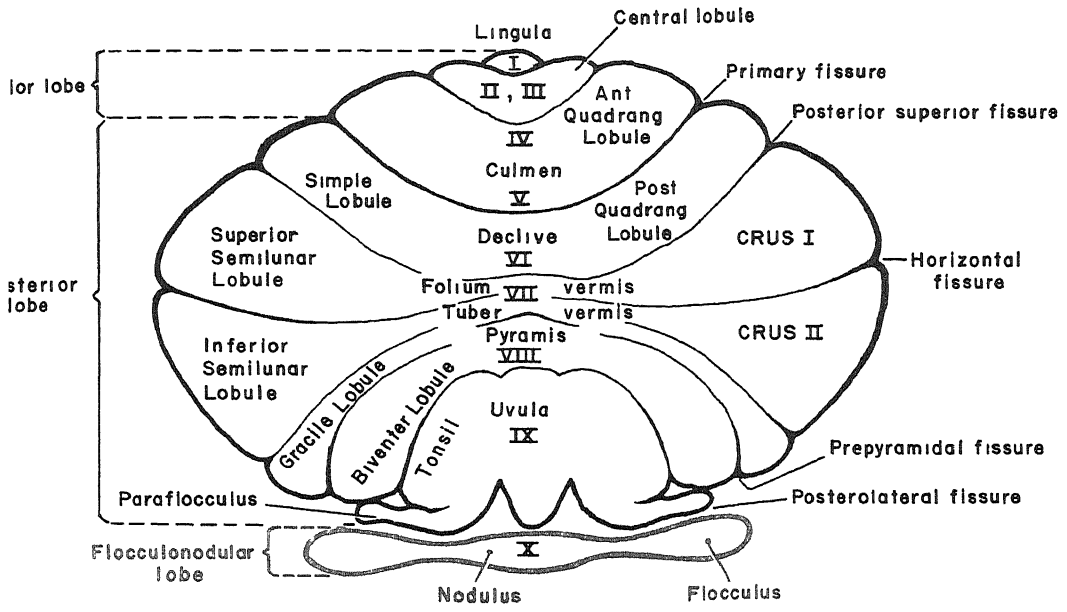

Fig 9 37 Subdivisions of the cerebellar cortex represented on an outline drawing From Trues and Carpenter 1969

ıns ıs not clear, however, and only a few of ı need to be remembered as landmarks narrow, central part of the cortex ıs called *vermis* ("worm"), and the two larger lat- masses are the right and left cerebellar *ıspheres* On the upper surface the demar- on between vermıs and hemıspheres ıs ıt Inferıorly ıt ıs more conspıcuous, and vermıs forms the roof of a depressıon wn as the *vallecula* that fits over the me- a oblongata Also ınferıorly ıs found an gated, somewhat lobulated structure on ı side called the *flocculus* ("tuft") that ıs ınuous with the most caudal or ınferıor of the vermıs, the *nodule* Together they ı the *flocculonodular lobe*, known as the ıcerebellum and believed to be the most ent part of the cerebellum from a phyloge- c poınt of vıew Its prıncipal functıonal tıonships are wıth the vestıbular nuclei of brainstem

he posterolateral fissure separates thıs lobe ı the rest of the cerebellum, the *corpus 'belli*, lyıng anterıor and superıor to the fis- ' Thıs fissure ıs one of a serıes of land- ks that run from sıde to sıde, from hemi- ere across vermıs to the other hemısphere, that consequently dıvide the cerebellum ı regıons that are eıther rostral, ıntermedi- or caudal ın theır locatıon Thıs type of dıvısıon ıs believed to be more sıgnıficant than gross anatomical dıvısıons, both phyloge- netically, embryologically, and from the vıew- poınt of comparatıve physıology (Fıg 9 37) The most ımportant fissure (asıde from the posterolateral fissure) ıs the *fissura prıma* of Elliot-Smith that dıvides the corpus cerebellı ınto a small anterıor and a larger posterıor lobe

Anterıor Lobe Thıs portıon, known as the paleocerebellum, consists of the lıngula and two other subdıvısıons of the vermıs, and the adjacent folıa of the rostral part of each hemı- sphere

Posterıor Lobe Thıs name ıs gıven to all of the rest of the cerebellar hemıspheres, ın- cludıng fıve parts of the vermıs, the majoı por- tıons of the hemıspheres themselves (the *ansi- form lobes*), the *paraflocculus*, and the *para- medıan lobule* or tonsıl, a small compact mass of cortex lyıng on eıther sıde of the ınferıor vermıs The ansıform lobule reaches ıts greatest development ın the human braın Its functıon ıs believed to be concerned wıth tonus adjustments and the muscular coordınatıon requıred for skılled movement

In hıgher anımals the posterıor lobe ıs fur- ther subdıvıded by a fissure known as the *sulcus* or fissura *prepyramıdalıs* Thıs ıs some- tımes used as a landmark for dıstınctıon be- tween the mıddle lobe of Ingvar lyıng between the fissura prıma and the sulcus prepyrami-

dalis, and a truly posterior lobe behind this sulcus and ahead of the posterolateral fissure Classified in this fashion the order of principal lobes and fissures from front to back is as follows

Anterior lobe (lingula, etc)
Fissura prima
Middle lobe of Ingvar
Sulcus prepyramidalis
Posterior lobe (pyramis, uvula)
Fissura posterolateralis
Flocculo-nodular lobe

The middle and posterior lobes, especially the ansiform lobes, belong to the neocerebellum, found only in higher animals In phylogenetic development they appear at about the same time as the cerebral cortex, the corticospinal and corticopontile tracts, and the pons The neocerebellum, cerebral cortex and pons are absent or rudimentary in forms below mammals

Neurons of the Cerebellum

When sectioned in the sagittal plane each hemisphere of the cerebellum presents a branching core of white matter which from its foliage-like appearance, has been named the *arbor vitae* The terminal branches of the white matter are covered with a coating of gray substance which constitutes the cerebellar cortex The leaflike structures so formed are spoken of as folia, and are responsible for the laminated appearance of the cerebellar surface (Fig 9 36) Unlike the cortex of the cerebrum all areas of the cerebellar cortex show a uniform histologic structure

CEREBELLAR CORTEX

The cells that lie in the cerebellar cortex have a pattern similar to the pattern of wall paper in that it is repeated and repeated throughout all of the folia (Fig 9 38) The units of each pattern include two types of fibers entering the grey matter, five types of neurons in the cortex, the glial cells, and the axons of the one cell (the Purkinje cell) that leave the cortex en route to cerebellar nuclei and brainstem This arrangement of elements was described by the great Spanish neuroanatomist, Ramón y Cajal, (1888) who studied sections stained with silver nitrate and examined under a conventional light microscope That more recent investigations using electron microscopy have not essentially altered the picture he described is a tribute to Cajal's skill and patience in preparing and examining sections

Three layers of the cortex have their characteristic appearance because they contain different proportions of cells and fibers, as follows

1) The *molecular* or plexiform layer (under a microscope it seems to have a very fine structure) is outermost It consists of unmyelinated fibers that enter the cerebellum from the inferior olive (the *climbing fibers*), axons from granule cells of the third layer, and dendrites of cells including the Purkinje cells (second layer) and Golgi type II cells (third layer) In the superficial part of the molecular layer where axons of granule cells are the most numerous there are only a few neurons, the small, star-shaped *superficial stellate* cells Deeper in this layer the stellate cells are larger, and they possess axons that run for some distance through this layer but across the folium at right angles to its long axis By means of collaterals they arborize around the bodies of a number of Purkinje cells located in a single plane of the folium (see Fig 9 38) Because of the appearance of these terminals, these stellate cells are known as *basket* cells

2) The *intermediate* layer of *Purkinje* cells The large, flask-shaped bodies of these cells, which are peculiar to the cerebellum, form a layer between the molecular and granular layers Terminals of the basket cells surround their cell bodies Their denrites pass outwards through the entire thickness of the molecular layer where they arborize luxuriantly, but only in two dimensions, like a fan in a single geometrical plane This plane is at right angles to the long axis of the folium The afferent *climbing fibers* make connections on these dendrites, and many of the axons of the granule cells of the innermost layer also end there The axons of the Purkinje cells enter the white substance, and end by synapsing with cells in the cerebellar nuclei and brainstem

The Purkinje cells have been referred to as the "final common pathway" of the cerebellar cortex, because it is through them that the cerebellum exerts its influence upon the central nuclei of the cerebellum, as well as upon other parts of the central nervous system As noted later, the Purkinje cells seem to be exclusively inhibitory in their action upon other neurons

3) The *granular* layer contains numerous

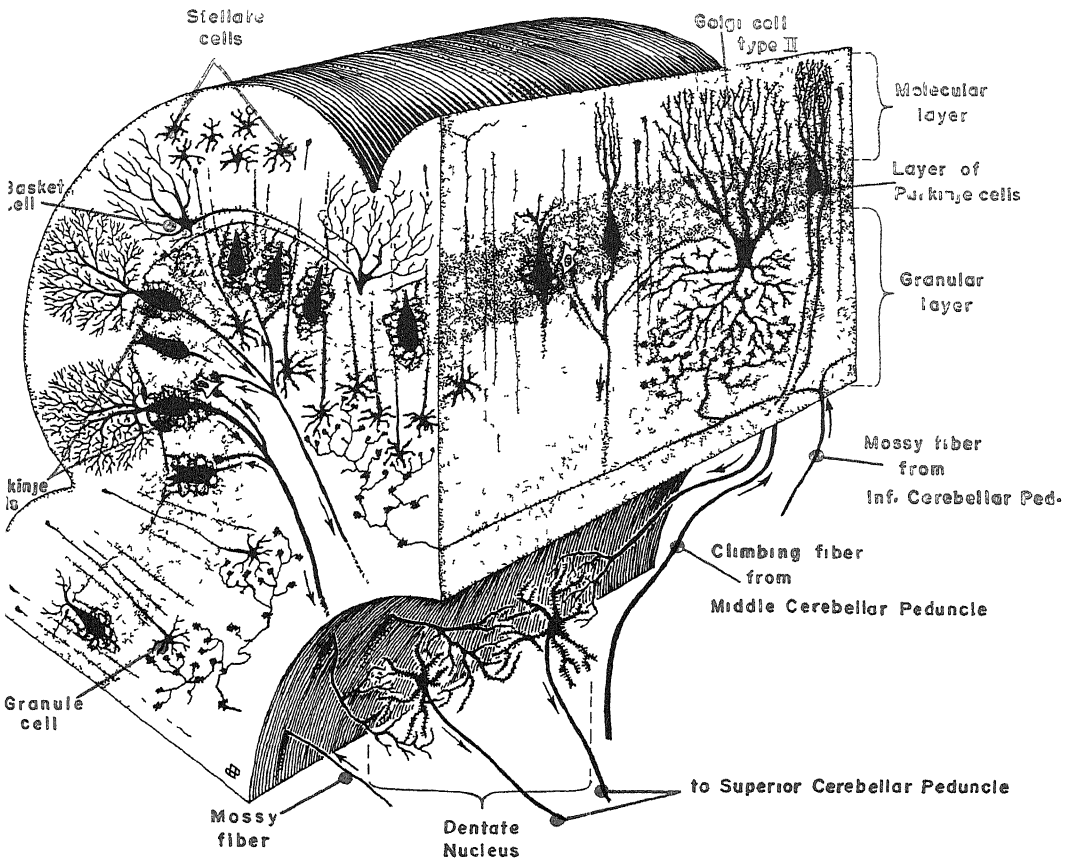

Fig 9 38 Cerebellar cortex drawn in three dimensions to show geometry of location of Purkinje cells Golgi s granule basket and stellate cells with terminals of climbing and mossy fibers

rve fibers, and the two remaining types of urons One is the *granule* cell, small, round, sely packed, and possessing four or five ndrites that end in a tuft of branches close the cell body and connect with terminals of ssy *fibers* and with axons of Golgi type II ls One long process (axon) extends out into molecular layer where it divides and sends branch in each direction along the length of folium These branches, therefore, pass ough the plane of arborization of the den- tes of many Purkinje cells The last type of uron is known as the *Golgi type II* cell be- use it has no long axon These are large cells ated in a plane just inside that of the Pur- nje cells They have dendrites that branch tensively in all planes of the molecular layer, d send their axons to branch repeatedly and d upon dendrites of the granule cells

The three types of fibers most essential to understanding of cerebellar function are the lowing

1) Mossy fibers are coarse, myelinated fibers that have a characteristic appearance as they terminate in the region of the terminals of granule and Golgi II cells in the granular layer of the cortex They are known to enter the cerebellum from the spinocerebellar systems, and are believed to come also from the pontocerebellar, vestibulocerebellar, reticulocerebellar, and other systems from the brainstem to cerebellar cortex (Eccles, et al , 1967)

2) Climbing fibers are also myelinated, but smaller, and have the unusual, ivy-like association with Purkinje dendrites already described They are believed to come largely if not exclusively from the olivary nuclei (Eccles, et al , 1967) These two types of fibers constitute the only known input to the cerebellum

3) Axons of the *Purkinje* cells are the sole output from the cerebellar cortex, they are small, myelinated fibers that run to the nuclei of the cerebellum, and to Deiter's nucleus of the vestibular complex These fibers, how-

ever, because most of them end within the cerebellum on its subcortical nuclei, are only a small fraction of the efferent output of the cerebellum as a whole Most of this output is carried by myelinated fibers originating in the central nuclei and carried to the brainstem and thalamus by superior and inferior peduncles

THE CEREBELLAR NUCLEI

The cerebellum contains on either side four separate gray masses (Fig 9 39) These are *a) nucleus fastigii* (nucleus of the roof), *b) nucleus globosus, c) nucleus emboliformis,* and *d) nucleus dentatus* (The nuclei globosus and emboliformis of primates are comparable to the nucleus interpositus of lower mammals) The first three of these are phylogenetically older than the nucleus dentatus, which is found only in mammals The fastigial nuclei, which are the most ancient of all, lie near the midline on either side in the roof of the 4th ventricle They receive fibers from the paleocerebellum (anterior lobe, pyramid, uvula, and flocculonodular lobe), and from the vestibular nuclei and eighth nerve through the inferior peduncle, they also project to the vestibular nuclei The globose and emboliform nuclei, which are placed more laterally than the roof nuclei, receive fibers chiefly from the anterior lobe The globose nucleus also receives fibers from the flocculonodular lobe Both nuclei project through the superior peduncles to the large-celled portion of the red nucleus The more lately acquired dentate nucleus, which is placed most laterally, is a large, crenated mass of gray matter, bent acutely upon itself It receives fibers from the Purkinje cells of the neocerebellum It projects through the superior cerebellar peduncle to the small-celled portion of the red nucleus (and to some extent also to the large-celled part), and to the ventrolateral group of the thalamic nuclei (Fig 9 39)

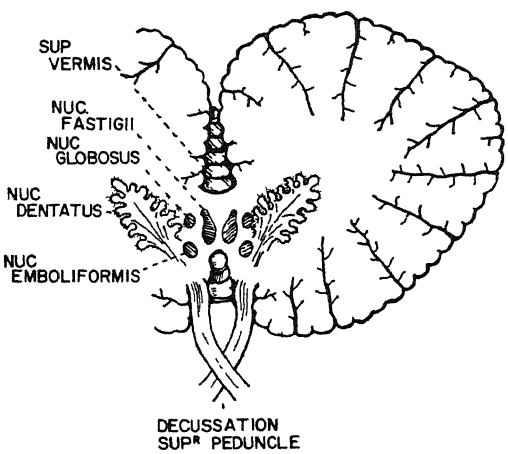

Fig 9 39 Diagram of a horizontal section through the cerebellum to show relation of cortex and subcortical nuclei, with superior peduncle and its decussation in the mesencephalon.

Connections of the Cerebellum

The white matter of the hemispheres is composed of *a) projection fibers,* i e , fibers which leave or enter the cerebellum via the peduncles, *b) association fibers,* which connect different regions of the same hemisphere, and *c) commissural fibers* connecting cortical areas of the two hemispheres

The *flocculonodular lobe,* mainly the nodule, is connected by both afferent and efferent fibers (some of which are relayed in the fastigial and globose nuclei) with the vestibular nuclei and the vestibular nerve The anterior lobes and the ansiform lobules receive spinocerebellar and pontocerebellar fibers, respectively, and project to brainstem and thalamic nuclei

The fibers, afferent and efferent, connecting the cerebellum with other portions of the nervous system are all carried in three large bundles, the *cerebellar penduncles,* having the following constitution

A) Inferior Peduncles (Restiform Bodies) they are predominantly afferent
- *1) Afferent Fibers*
  - *a)* Dorsal (posterior) spinocerebellar tract (the direct cerebellar tract)
  - *b)* Dorsal external arcuate fibers
  - *c)* Ventral external arcuate fibers
  - *d)* Vestibulocerebellar fibers
  - *e)* Olivocerebellar tract, the fibers of which end in all parts of the cerebellar cortex as climbing fibers upon dendrites of Purkinje cells
  - *f)* Fibers from the fifth cranial nerve, and possibly from the ninth and tenth, to pyramid, uvula and paraflocculus
- *2) Efferent Fibers*
  - *a)* Fastigiobulbar (or cerebellovestibular) tract
  - *b)* Cerebello-olivary tract to inferior olives of both sides

They also have an excitatory action on the basket cells and the dendrites of the Golgi type II cells According to these authors this is a complete account of excitatory effects within the cortex, they involve three kinds of axons, climbing fibers, mossy fibers, and granule cell fibers All other actions are of an inhibitory nature

The *inhibitions* they have identified include the following

1) Purkinje cells are inhibitory upon cells of subcortical cerebellar nuclei and upon Deiter's nucleus,

2) Basket cells are inhibitory upon Purkinje cells,

3) Golgi type II neurons are inhibitory upon the mossy fiber-granule cell synapse

These observations suggest that the overall influence of the cerebellar cortex upon subcortical nuclei is one of inhibition, but that this inhibition is graded by the neuronal actions that simultaneously excite and inhibit the discharge of Purkinje cells

In addition to this complex interrelation of excitation and inhibition, another interesting feature of cerebellar cortical activity is the geometric pattern it assumes, in which the orientation of the plane of arborization of Purkinie cells in the folium is like slices of bread in a long loaf The distribution of axons of basket cells is in similar planes across the long axis of the folium The distribution of parallel fibers from granule cells, however, is along the length of the folium and therefore across the planes of Purkinje cells and basket cell axons The dendrites of the Golgi type II cells branch out in all planes of the molecular layer

EXPERIMENTAL STUDY OF THE CEREBELLUM

The cerebellum seems to be relatively simple because *a*) the pattern of cortical organization is straightforward and repeated throughout the folia, *b*) the cortex receives only the input of mossy and climbing fibers, *c*) there are only five types of neurons in the cortex, and *d*) the cortex and subcortical nuclei have a constant relationship by way of axons of Purkinje cells Nevertheless, the multitude of connections between cerebellum and the spinal cord, the tegmentum of the brainstem, olivary complex, vestibular nuclei, red nucleus, thalamus, and cerebral cortex has made analysis of its functions exceedingly difficult In the first place, there is no lack of information about these possible extrinsic connections, the course of almost innumerable fibers has been described with great care, with the result that on this basis alone it is impossible to conceive of any simple pattern of cerebellar control of motor activity Second, there is no lack of observations as to the deficiencies that follow cerebellar injury in both human patients and laboratory animals Third, unlike other portions of the brain, stimulation of the cerebellar cortex in anesthetized animals does not induce motor responses that lend themselves to easy interpretations In spite of these problems, however, one should try to understand the nature of the principal cerebellar functional relations, the general character of deficits that follow ablation or injury, and possible explanations for the results of stimulation experiments This information is summarized in chapter 5 beginning on p 9-98

SUBCORTICAL MECHANISMS OF THE TELENCEPHALON

The Basal Ganglia

The basal ganglia form a large and prominent part of the human brain, and are a very important part of the nervous mechanisms controlling muscular activity (Fig 9 41) Destructive lesions in the human basal ganglia are associated with several well known, common, severe motor disorders which are fairly constant in their clinical pattern Yet, our knowledge of the nervous connections and of the functional activity of the human basal ganglia is grossly deficient They have grown proportionately from the lower primates to

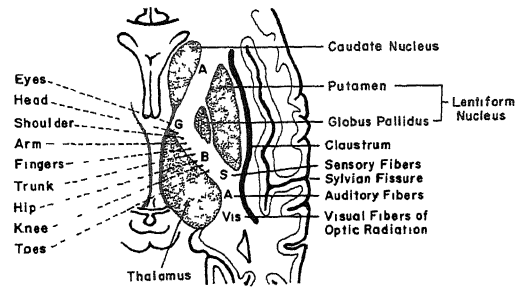

Fig 9 41 Horizontal section through right cerebral hemisphere showing relationships of thalamus internal capsule and basal ganglia including caudate nucleus, lentiform nucleus and claustrum Localization of fibers in internal capsule is also shown

man, so that whereas the globus pallidus, putamen and caudate nucleus occupy 980 cu mm in the rhesus monkey, they measure 2775 mm ^{3} in the chimpanzee and have a volume of 14,912 mm ^{3} in man (Harman and Carpenter, 1950)

NUCLEAR GROUPS

In this discussion the term "basal ganglia" will be used to include the *caudate nucleus*, the *putamen*, and the *globus pallidus* of the telencephalon, the *subthalamic body of Luys* of the diencephalon, and the *red nucleus* and the *substantia nigra* of the mesencephalon (The caudate nucleus and putamen are often referred to as the *striatum* and the globus pallidus as the *pallidum* The putamen and globus pallidus are sometimes referred to as the *lenticular* or *lentiform nucleus*) The *claustrum* should also be included in the basal ganglia but as practically nothing is known of its connections or functions it need not be considered further It might be argued that the subthalamic body, the red nucleus, and the substantia nigra should not be included, but their anatomical relationships, their numerous connections, and their apparent close functional relationships with the other nuclei of the basal ganglia make their inclusion natural and reasonable The amygdala is another subcortical collection of neurons that might be included But it has no known connections with the functions of the skeletal muscular system and seems more likely to be related to vegetative activities

The cytology of the various nuclei under discussion offers little assistance in understanding their functional activity For the most part the nuclei seem to be divided into two groups—the small-celled and the large-celled parts As is true of the cerebral cortex the small-celled parts appear to be the receptive divisions of the basal ganglia, whereas the large-celled parts have a predominantly motor function The caudate nucleus and the putamen constitute the receptive portion and are said to receive their afferent innervation from the precentral motor cortex (areas 4, 4s, and 6), the suppressor strips of Dusser de Barenne and his co-workers (areas 4s, 8, 2, and 24), (Fig. 9.42) and in a small way from the thalamus. In turn the caudate nucleus and putamen send their efferent fibers mainly to the large-celled or "motor" portion of the lenticular nucleus, the globus pallidus (Fig 9 42), with a much smaller group of efferent fibers going to the substantia nigra Similarly the substantia nigra is divided into a large-celled (pigmented) dorsal portion and a small-celled (unpigmented) ventral portion which lies just above the cerebral peduncle The red nucleus, too, is divided into a small-celled anterior portion and a large-celled posterior portion which gives rise to the rubrospinal tract

As noted above (p 9-29), in the dog and cat the magnocellular portion of the red nucleus and the rubrospinal tract are large and presumably important structures, whereas in the primates this portion of the red nucleus and the rubrospinal tract which arises from it are small and apparently insignificant (Stern, 1936, Massion, 1967) The parvocellular or main portion of the nucleus in man has a variety of connections, most of them related to the dentatorubrothalamic pathways that send fibers through and around the red nucleus on their way from cerebellar nuclei to the lateral ventral nuclei of the thalamus

CONNECTIONS

Within the basal ganglia almost all parts are connected with all other parts (Fig 9 42), i e, the globus pallidus sends fibers to the red nucleus, and substantia nigra and the subthalamic nucleus, the substantia nigra sends fibers to the red nucleus, the globus pallidus and the subthalamic nucleus, the subthalamic nucleus sends fibers to the globus pallidus, red nucleus and the substantia nigra Within the basal ganglia there are also recurrent systems, such

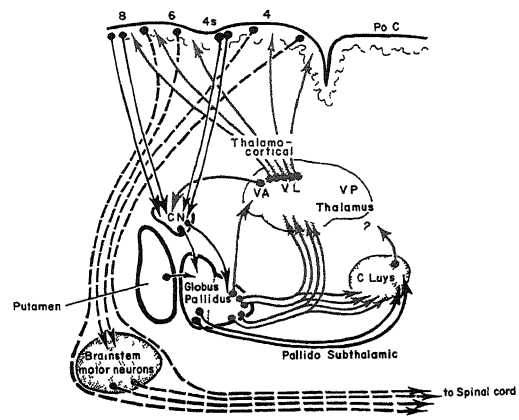

Fig 9 42 Outline of pathways by which basal ganglia are interconnected and related to motor mechanisms of cerebral cortex and brainstem and spinal cord

as the projection from the caudate nucleus to the globus pallidus, the globus pallidus to the ventral anterior nucleus of the thalamus, and from this thalamic nucleus back to the caudate nucleus (Fig 9 42) Two parts of the basal ganglia, however, remain more or less aloof from this intranuclear activity They are the caudate nucleus and putamen, and the red nucleus The caudate nucleus and putamen on the one hand receive their afferent innervation largely from the cerebral cortex (with additional afferent connections from the substantia nigra and from the ventral anterior nucleus of the thalamus), and they distribute their efferents to the globus pallidus and the substantia nigra The red nucleus receives from all of the other nuclei of the basal ganglia (and from the precentral motor cortex and the cerebellum) but sends all of its efferent fibers to structures outside of the basal ganglia, to the spinal cord, the reticular substance of the brainstem, the ventrolateral nucleus of the thalamus, the inferior olive and the oculomotor nuclei (Fig 9 43) Thus, the caudate nucleus and the putamen appear to be acting as the primary receiving station of the basal ganglia, whereas the red nucleus and the globus pallidus are acting as the principal sending stations In addition to their efferent fibers there are fibers from the substantia nigra and the subthalamic nucleus to the substantia reticularis and the centermedian nucleus of the thalamus

Internal Capsule

If one considers the very large number of cells in the cerebral cortex capable of acting upon motor mechanisms of brainstem and spinal cord, together with projections to basal ganglia, thalamus, pons, and cerebellum, it becomes obvious that pathways for transmission of these influences must be plentiful They leave the cortex via the central white substance of the hemispheres, the region that contains also the fibers ascending to the cortex, and fibers running to and from the corpus callosum As the corticofungal fibers descend toward the level of the mesencephalon, they run past the basal ganglia of the telencephalon, and also skirt the lateral and ventral sides of the thalamic collections of neurons From the level of the central white substance all the way down to the spinal cord these corticospinal pathways remain separate from the parts of the brain through which they are passing, except for collaterals given off in transit

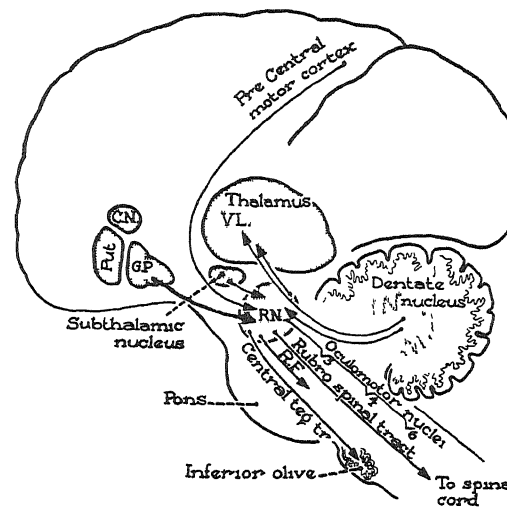

Fig 9 43 Connections of the red nucleus Abbreviations refer to principal basal ganglia *R F* denotes fibers to reticular formation

In its longitudinal organization the central nervous system contains two parallel systems One is what appears to be the modulating system that functions as a control for the other system, and that includes the reticular substance of tegmentum and hypothalamus, the thalamic nuclei of midline and intralaminar location, the basal ganglia, and the cerebral-pontile-cerebellar-thalamic complex The other includes the long ascending and descending systems, with ascending relays in dorsal grey columns of spinal cord, in the brainstem, and in the thalamus, and with descending relays that always seem to be diversions from the main tracts into nuclei or neuronal groups encountered along the way The internal capsule is the broad highway in both directions between the cerebral cortex and subcortical and spinal centers In a horizontal section of the cerebrum it is seen as a compact band of white matter lying between the thalamus and caudate nucleus on its inner aspect and the lenticular nucleus on its lateral aspect (cf Fig 9 41) In addition to the corticospinal and corticobulbar tracts the following are the principal tracts which compose it

I) Descending

a) Corticopontine tracts consisting of three bundles of fibers, *frontopontine*, *parietopontine*, and *occipitopontine* from the corresponding areas of the cerebral cortex to the nuclei of the pons

b) *Corticorubral tract*, from the frontal lobe to the red nucleus
c) *Corticothalamic* from almost all areas of the cortex to various nuclei of the thalamus
d) *Corticostriatal fibers* from the precentral area of the cortex to the caudate nucleus and the globus pallidus
e) *Occipitotectal fibers* from the para- and peristriate cortex to the tectum of the midbrain
f) *Corticonigral fibers* from the precentral and temporal areas to the substantia nigra

II) Ascending
a) *Thalamic radiations* consist of four bundles ascending from the thalamus, *anterior*, *superior*, *posterior*, and *inferior*, which connect the thalamus with various parts of the cerebral cortex The anterior group terminate in prefrontal areas, and the superior group in the somesthetic area (postcentral gyrus)
b) *Auditory radiation fibers* ascending from the medial geniculate body to the temporal cortex (geniculotemporal fibers)
c) *Optic radiation fibers* ascending from the lateral geniculate body to the visual area in the occipital cortex (geniculocalcarine) fibers
d) *Rubrocortical fibers* from the red nucleus to the cortex

The internal capsule is bent in the horizontal plane to conform a convexity directed medially The region of the angle so produced is called the knee (genu), the portions in front and behind this are known, respectively, as the anterior and posterior limbs The shorter anterior limb lies between the caudate nucleus and the lenticular nucleus, the posterior limb between the lenticular nucleus and the thalamus The extension backwards of the posterior limb is known as the *retrolenticular part*

The anterior limb is occupied by the frontopontine fibers and the anterior thalamic radiation (thalamofrontal fibers), the frontothalamic tract, corticostriatal and corticorubral tracts In the anterior three-fifths of the posterior limb are transmitted the corticobulbar and corticospinal fibers The fibers of these two tracts are organized in accordance with the portions of the body which they innervate, those carrying impulses for the eye muscles, the muscles of the tongue, and face and upper and lower extremities arranged in this order from before backwards, and those transmitting impulses destined for the proximal part of an extremity are placed in front of those for the more distal muscles The remaining part of the posterior limb, and the retrolenticular part carry in anteroposterior order the superior and posterior thalamic radiations, the auditory (geniculotemporal), and the inferior thalamic radiations, corticothalamic, and parietopontine fibers, and the optic (geniculo-occipital) radiations

The internal capsule is supplied with blood through the lateral striate branches of the middle cerebral artery, by the recurrent artery of Hubner from the anterior cerebral artery, and the anterior choriodal artery from the internal carotid artery The internal capsule is frequently a site of injury to the nervous system through hemorrhage from one of the striate branches Both sensory and motor deficits may result

3 / CONTROL OF SMOOTH MUSCLE AND EXOCRINE GLANDS

Before a description of the mechanisms controlling skeletal muscle is attempted, it will be instructive to consider the control of smooth muscle and exocrine glands, for two reasons First, these latter controls are less complex than the other, second, an explanation of the organization of the autonomic system and how it functions will include topics such as chemical transmission of nerve impulses that are relevant to all neural controls The characteristics of the autonomic system that seem to make it unique can be shown to be merely overstated displays of how neural systems are put together The one really unique feature of such systems turns out to be the fact that smooth muscle can, but skeletal muscle cannot be inhibited by a mechanism acting directly upon it

Terminology and Organization

Smooth muscle and glands are controlled by systems that have both afferent and efferent components, although in the history of studies on these systems the efferent components have been given more attention than the afferent To understand the literature on these controls, it is necessary first of all to grasp the distinctions between terms used to designate parts of the system The most comprehensive of these terms is the *autonomic* nervous system, a name utilized some seventy years ago by the Cambridge physiologist, J N Langley (1903, 1921) A few years later his colleague, W H Gaskell (1916), employed the term *involuntary* nervous system as a synonym Both of them wrote primarily of the motor components (Fig 9 44) In the most recent literature, on the other hand, both the words autonomic and also *visceral* are employed to include both sensory and motor innervations of visceral structures, specifically, of smooth muscle and glands

In the years that followed the work of Gaskell and Langley, additional names were given to the principal subdivisions of the motor side of the visceral system From this much of the confusion of terminology arose, because the ancient anatomical name, *sympathetic*, was redefined and used with *parasympathetic* to denote two supposedly opposed portions of the system These terms were popularized especially in the United States by publications from the laboratory of Walter Bradford Cannon of Harvard (1929, 1932), and thence came into general use without precise definition In response to this lack of precision, two more specific classifications were developed, one anatomical in which the two subdivisions are *craniosacral*, and *thoracolumbar*, named for the site of origin of efferent fibers The other classification was originally pharmacological, with *adrenergic* and *cholinergic* utilized to identify fibers with reference to their chemical transmitter Unhappily, these three sets of terms cannot be used interchangeably, although they have superficial characteristics that suggest that they might be The term, sympathetic, has come to have a philosophical, almost mystic meaning It is to a degree synonymous with the thoracolumbar division, and many of its terminals are adrenergic But it contains also certain important cholinergic terminations The craniosacral division is the same as the parasympathetic portion, and all of its fibers are cholinergic These usages are summarized as follows

Terminology	Divisions	
Anatomical	Craniosacral	Thoracolumbar
Physiological	Parasympathetic	Sympathetic
Pharmacological	Cholinergic	Cholinergic and Adrenergic

Autonomic control systems are constituted from detector (afferent) neurons, connector or interneurons, and efferent or effector neurons in the fashion outlined in chapter 1. There are two curiosities, however, about the location of these neurons Whereas interneurons in general are located exclusively in spinal cord or brain, the last interneuron of the autonomic motor system sends its process through the ventral roots or via a cranial nerve to termi-

nate in one of the ganglia of the autonomic system (Fig 9 45) This means that without exception the efferent or effector neuron has its location in one of these ganglia—either in a ganglion of the sympathetic chain (cervical, thoracic, lumbar, or sacral), in a so-called "collateral" ganglion lying near a major blood vessel (e g , coeliac, superior mesenteric), or in a terminal ganglion lying in, on or near the viscus innervated These relations, again, sometimes give rise to confusion, inasmuch as the connector neuron is known as the *preganglionic* neuron, the effector as the *postganglionic* neuron, and homology with the somatic motor system is thereby obscured

AFFERENT VISCERAL NERVES

Impulses are transmitted from the viscera by afferent fibers which pass through the various plexuses and reach the central nervous system via the vagus, pelvic, splanchnics, and other autonomic nerves

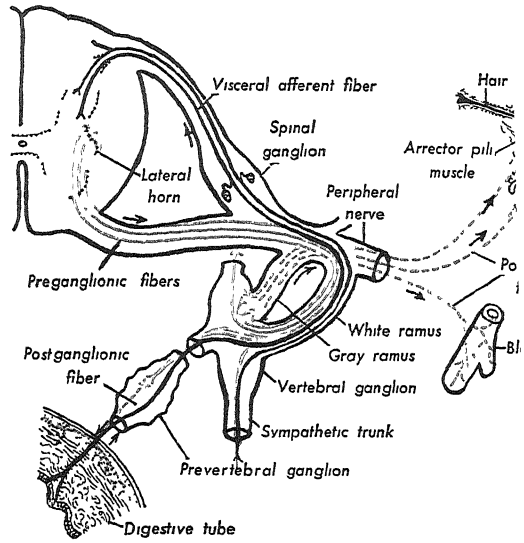

Fig 9 45 Diagram showing course of visceral afferent and efferent fibers in dorsal and ventral roots respectively and their distribution through the thoracolumbar system Copenhaver cited from Truex and Carpenter 1969

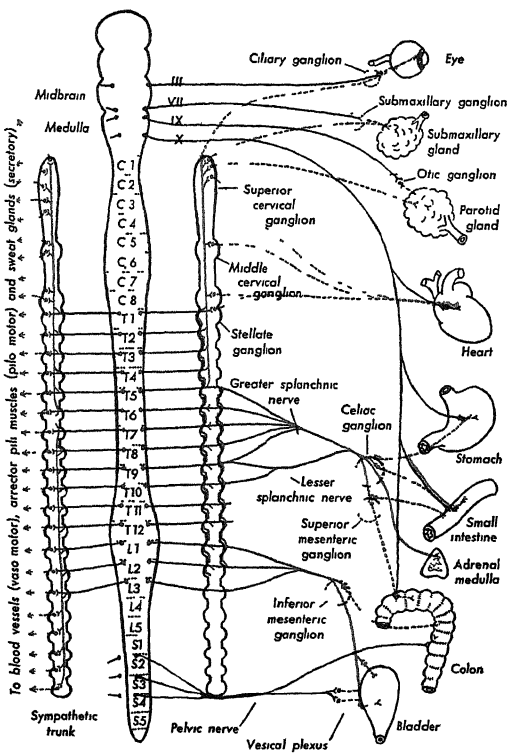

Fig 9 44 Diagram of connections of autonomic or visceromotor system Craniosacral components are in black, thoracolumbar connections are in brown Course of postganglionic fibers is shown by broken lines (Truex and Carpenter 1969)

The *afferent fibers of the thoracolumbar division* are the peripheral processes of ganglion cells in the posterior spinal root ganglia from the 1st thoracic to the 3rd lumbar segments None arises from sympathetic ganglia They reach the sympathetic trunk via the white rami communicantes and are distributed to the viscera along with the corresponding efferent fibers (Fig 9 45) Though some of these afferent fibers are nonmedullated, the majority are medullated, and of larger size than the efferent fibers The ganglion cells of the posterior roots which give origin to the visceral afferent fibers have not been shown definitely to differ from those giving rise to the ordinary somatic sensory fibers. The afferent fibers pass to their destinations without interruption in any of the sympathetic ganglia, passing directly to the viscera in the splanchnics or the other visceral nerves A certain proportion also enter the spinal nerves for distribution to the limbs via the gray rami

The *afferent fibers of the* cranial division are the peripheral processes of cells in the ganglia of nerves VII, IX, and X The central processes of these neurons terminate in the nucleus of the tractus solitarius The *afferent fibers of the pelvic nerve* arise from cells in the posterior root ganglia of the 2nd, 3rd, and 4th sacral

nerves They pass peripherally with the efferent autonomic fibers

A certain degree of independent reflex activity has been attributed to the intrinsic plexuses, e g , of the intestine, when these are separated from the central nervous system by division of the main autonomic nerves It is also true that some independent activity can be carried out through axon reflexes or possibly through some of the more peripherally placed ganglion cells Other parts of the autonomic system, however, cannot function apart from the central nervous system The larger ganglia of the parasympathetic or sympathetic, for instance, do not serve as reflex centers It is clear from the description of the origin and course of the visceral afferent nerves given above that no anatomical basis for such action exists

Sympathetic Motor Division

Cells of origin of the sympathetic division are situated in the lateral horns of the spinal cord (intermediolateral cell column) from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar segments The axons of these preganglionic cells leave the cord by the corresponding anterior nerve roots and synapse with postganglionic nerve cells in one or another of the outlying ganglia Preganglionic fibers are myelinated, postganglionic fibers have no myelin sheath

The ganglion cells are all motor or secretory in function, they have no afferent connections from the periphery Afferent fibers from the various viscera and blood vessels that pass through the sympathetic nervous system have their ganglion cells in the posterior root ganglia, as described above

The motor ganglia are arranged in three systems or groups *A) paravertebral, B) prevertebral* (or *collateral*), and *C) terminal* (or *peripheral*)

PARAVERTEBRAL GANGLIA AND THE GANGLIONATED CORD

Ganglia of the paravertebral group lie in close relation to the vertebral bodies On each side, there is a series of some 22 ganglia connected together by intervening fiber tracts to form a nodular cord extending from the base of the skull to the front of the coccyx This is known as the *sympathetic chain* or the *ganglionated cord of the sympathetic nervous system* All but the lowest four of these (the sacral ganglia) belong to the thoracicolumbar division It will be described in sections

Cervical Part of the Sympathetic Chain The cervical part of the sympathetic chain possesses three ganglia—the *superior, middle,* and *inferior cervical ganglia* They are relatively large and are believed to result from the fusion of two or more smaller ganglia

The Superior Cervical Ganglion, situated below the base of the skull, is the largest of the three It receives preganglionic fibers from the upper thoracic segments of the spinal cord, and its cells supply fibers (postganglionic) to the vessels, glands, and cutaneous muscle of the head It is probably formed by the fusion of the uppermost three or four cervical ganglia

Middle Cervical Ganglion is formed presumably by the coalescence of the 5th and 6th cervical ganglia Its branches include fibers to the *5th and 6th cervical nerves* and thence to the blood vessels, sweat glands, and cutaneous muscle within the area of distribution of these nerves, *the middle cardiac nerve* to cardiac plexuses, and branches which extend along the inferior thyroid artery to the *thyroid* and *parathyroid glands*

Inferior Cervical Ganglion probably represents the union of the 7th and 8th cervical ganglia, in the dog and cat, and in most human subjects, it is usually fused with the first thoracic ganglion, and occasionally with the second as well, to form the so-called *stellate ganglion* It gives off branches to the *7th and 8th cervical* and the *1st thoracic nerves,* sometimes also to the 6th cervical and the 2nd thoracic, the *inferior cardiac nerve* to cardiac plexuses, and branches which form plexuses upon the subclavian artery and its branches Sympathetic fibers are thus carried into the cranial cavity along the vertebral artery, and over the axillary and commencement of the brachial

Thoracic, Lumbar and Sacral Ganglia. The *thoracic ganglia* are 10 or 12 in number on each side They are evenly spaced, one to each spinal segment As mentioned the first thoracic and inferior cervical ganglia are commonly partially or completely fused to form an irregularly shaped mass, called the *stellate ganglion* There are usually 4 *lumbar,* in addition to 4 or 5 *sacral* ganglia The sacral portions of the two sympathetic trunks converge

below and fuse upon the anterior surface of the coccyx to form a terminal swelling—the *coccygeal ganglion* or *ganglion impar*

PREVERTEBRAL (OR COLLATERAL) GANGLIA

These lie in the thorax, abdomen, and pelvis in relation to the aorta and its branches (Fig 9 46) The larger of the prevertebral ganglia are *a*) the *celiac* (*solar* or *semilunar*) *ganglion*, lying in relation to the origin of the celiac artery, *b* the *superior mesenteric ganglion*, situated below the origin of the superior mesenteric artery, and *c*) the *inferior mesenteric ganglion*, which bears a corresponding relation to the inferior mesenteric artery, this ganglion is rarely present in man

TERMINAL GANGLIA

These consist of small collections of ganglion cells situated in close relation to the innervated organs, especially those of the pelvis, e g , the bladder and rectum

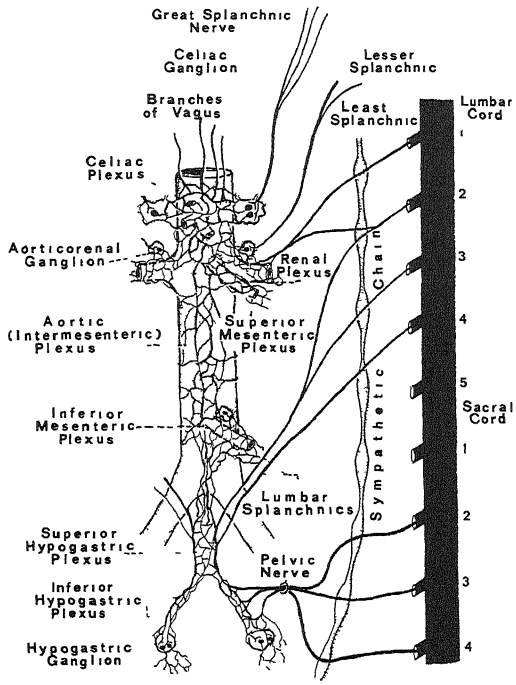

Fig 9 46 Diagram of nerve plexuses of the abdomen and pelvis

OUTFLOW OF SYMPATHETIC FIBERS FROM THE CENTRAL NERVOUS SYSTEM

It has already been stated that the cells giving rise to the thoracicolumbar, preganglionic fibers are situated in the thoracic and upper lumbar segments of the cord This limited region (8th C or 1st T to 2nd or 3rd L inclusive) constitutes the only outlet for sympathetic impulses The fibers emerge from the spinal cord through the anterior root of the spinal segment in which their cell bodies are placed In a cross-section of the anterior root they appear as fine medullated fibers (2 5μ or less in diameter) intermingled with the larger, medullated, somatic (motor) fibers They separate almost immediately, however, from the somatic motor fibers of the anterior root, and enter the corresponding ganglion of the sympathetic chain Thus, the spinal nerves from the 8th cervical or 1st thoracic to the 2nd or 3rd lumbar, but not others, are connected each to a paravertebral ganglion by a delicate white strand composed of preganglionic fibers and known as the *white ramus communicans* (plural, *rami communicantes*) A preganglionic fiber after entering the ganglion may pursue one of three courses it may *a*) form synapses with cells in the ganglion which it first enters, or *b*) traverse the ganglionated cord without interruption to find a cell station in either a prevertebral or a terminal ganglion, or *c*) pass up or down the sympathetic trunk for some distance to terminate in a ganglion at a level higher or lower than the segment from which it originated It may give off collateral branches to ganglion cells along its course In any event, the preganglionic fibers issuing from a given segment connect with several ganglia (from five to nine) Furthermore, each preganglionic fiber may form a large number of synapses within a given ganglion Ranson and Billingsley (1918) found that in the case of the superior cervical ganglion each fiber communicated with some 32 ganglion cells, this accounts for the diffuse nature of the sympathetic discharge

DISTRIBUTION OF SYMPATHETIC FIBERS TO THE PERIPHERY

Ganglia of the sympathetic chain are connected with the spinal nerves supplying the limbs and trunk by delicate filaments called *gray rami communicantes* They are composed of the axons of the ganglion cells in the para-

vertebral ganglia, and are therefore called *postganglionic* The gray rami in the thoracic and upper lumbar regions join the spinal nerves close to the points at which the white rami arise Their constituent fibers are continued in the peripheral nerves for the supply of the blood vessels, sweat glands, and smooth muscle of the skin Whereas, as already mentioned, only a limited number of spinal nerves possess white rami, *every spinal nerve receives a gray ramus* It therefore follows that sympathetic impulses going to parts supplied by upper cervical, lower lumbar or sacral somatic nerves, must travel considerable distances up or down the sympathetic trunk before reaching an outlet through a gray ramus To the limbs and trunk the preganglionic fibers to the upper limb arise from the 2nd to the 7th thoracic spinal segments, most of these fibers are contained in the white rami of the 2nd and 3rd thoracic anterior roots The postganglionic fibers to the upper limb may arise from the upper 1st to 4th thoracic, and the inferior and middle cervical ganglia, those for the lower limb from the lumbar and sacral ganglia Excision of the inferior cervical or the stellate ganglion when present and the upper three or four thoracic ganglia provides as complete a postganglionic sympathectomy as it is possible to make of the upper limb, as well as the head and neck It also will destroy most of the postganglionic fibers to the heart This operation, however, may fail to remove completely the sympathetic supply to the arm since there may be "intermediate" ganglia which are not removed in such an operation

Parasympathetic or Craniosacral Motor Division

The cells giving rise to parasympathetic fibers are situated at three different levels of the central nervous system—the *midbrain*, the *medulla oblongata*, and the *sacral region of the spinal cord* The axons of these cells leave the central nervous system to connect with ganglion cells lying within or in close relation to the innervated organ As in the case of the sympathetic division the axons of the central cells are called *preganglionic*, those of the ganglion cells, *postganglionic* The former are medullated, the latter nonmedullated The three levels from which parasympathetic fibers emerge will be referred to as the *tectal* (or *midbrain*), the *bulbar* and the *sacral* outflows, respectively

TECTAL OR MIDBRAIN OUTFLOW

The group of cells composing the Edinger-Westphal nucleus of the oculomotor nerve in the mesencephalic part of the intermediate motor column give rise to fibers that are conveyed in the third nerve as far as the ciliary ganglion where they find their cell stations Postganglionic fibers emerge from the ganglion in the short ciliary nerves, and terminate in the sphincter pupillae and the ciliary muscles

BULBAR OUTFLOW

These fibers leave the brain in the *facial*, *glossopharyngeal*, and *vagus nerves*

1) The parasympathetic fibers (secretory and vasodilator) entering the *facial nerve* arise from the *superior salivatory* (*salivary*) *nucleus*, which lies dorsal and lateral to the lower end of the motor nucleus of the facial [1] These fibers emerge from the brain in the sensory root of the facial nerve (*nervus intermedius*) and travel with the latter to the facial canal of the temporal bone Here they leave the facial *i*) They may join its *chorda tympani* branch which later joins the lingual to be conveyed to the floor of the mouth At this point some of the chorda fibers (secretory and vasodilator in function) separate from the lingual again to enter the *submaxillary* (*submandibular*) *ganglion* from where they are relayed, the postganglionic fibers pass to the submaxillary and submandibular glands, and the mucous membrane of the mouth *ii*) They may run with the great superficial petrosal nerve and nerve of the pterygoid canal (Vidian nerve) to the sphenopalatine ganglion From here postganglionic fibers pass via orbital branches of the ganglion to the lacrymal gland, and to the mucous membrane of the soft palate, nasopharynx and pharynx via the palatine nerves Vasodilator fibers also leave the facial by the great superficial petrosal nerve, and entering the cranium are conveyed along the middle meningeal artery and its branches

2) The parasympathetic fibers (secretory and vasodilator) of the *glossopharyngeal nerve* arise from cells of the *inferior salivatory* (*sali-*

[1] This nucleus is actually in the lowest part of the pons

vary) *nucleus* This nucleus lies in the uppermost part of the medulla oblongata immediately below the superior salivatory nucleus, and lateral to the motor nucleus of the glossopharyngeal nerve The autonomic fibers leave the brain with the latter nerve but separate from it again in its tympanic branch (Jacobson's nerve) which joins a twig from the geniculate ganglion (g of facial nerve) and filaments from the internal carotid plexus to form the *tympanic plexus* From this plexus emerges the *small superficial petrosal nerve* through which parasympathetic fibers are continued to the otic ganglion From this ganglion postganglionic fibers are conveyed to the parotid gland via the auriculotemporal nerve The tympanic plexus itself sends filaments to the mucous membrane of the tympanic cavity, the mastoid air-cells, auditory (Eustachian) tube, and the internal ear

3) The *vagus nerve* contains the greater proportion of the fibers of the bulbar outflow They arise from the *dorsal motor nucleus* of the vagus and are distributed through the latter's numerous branches to the thoracic and abdominal viscera (chap 2) Unlike those in the other two cranial nerves, the preganglionic fibers of the vagus connect with ganglion cells situated within the innervated organs Thus, the vagal fibers to the heart connect with ganglion cells in the cardiac walls those to the bronchi with the nerve cells of the intrinsic plexus in the bronchial walls, those to the esophagus, stomach, and intestine form synapses with the ganglion cells of the myenteric plexus of Auerbach and the submucous plexus of Meissner The preganglionic fibers are therefore quite long, the postganglionic very short, and the analogue of the terminal ganglia may be represented as relatively small collections of postganglionic neurons The cells of origin of most of the cardiac fibers of the vagus form a discrete group (cardioinhibitory center) lying alongside the dorsal nucleus of the vagus

SACRAL OUTFLOW

The cells of origin lie in the intermediate columns of the 2nd, 3rd and 4th, and sometimes the 1st sacral segments of the spinal cord The preganglionic fibers emerge in the anterior roots of the corresponding sacral nerves, then leave the spinal nerves again and, proceeding peripherally as the *pelvic nerve* (or *nervus erigens*), on each side, enter into the formation of the pelvic plexus The fibers terminate around ganglion cells lying in close relation to the pelvic organs They carry motor impulses to the walls of the descending colon, rectum, and bladder, inhibitory impulses to the internal anal and visical sphincters and to the uterus, and dilator impulses to the blood vessels of the bladder, rectum, and genitalia

Functions of the Autonomic Nervous System

Because the autonomic nervous system transmits information to the spinal cord and brain from the viscera, and because it provides a significant part of the motor control of all cardiac and smooth muscle, of exocrine glands and possibly of certain endocrine organs, its function may be designated as visceral control It is not, however, the sole means of such control, inasmuch as the digestive tract, for example, has an elaborate pattern of control based upon intrinsic and extrinsic hormonal mechanisms A complete account of the control of digestion, therefore, must include both neural and hormonal components They are alike in that both appear to be "involuntary," operating without conscious awareness of their activity They are nevertheless interdependent, and both are under the influence of the central nervous system

Through its various activities the autonomic system contributes to the maintenance of the constancy of composition of the fluid environment of the body's cells, it serves to combat forces, acting either from within or without, which tend to cause variations in this environment Regulation of the composition of the body fluids and their temperature, quantity, and distribution is effected through the actions of the autonomic nerves upon circulatory, respiratory, excretory, and glandular organs For example, of glandular structures under autonomic influence, the liver, pancreas, and adrenal medulla are of especial importance in the regulation of blood sugar, the sweat glands aid in the control of body temperature The stability of the internal environment (the *milieu interne* of Claude Bernard) which is so characteristic of the healthy body, was designated by Cannon as *homeostasis*. According to Cannon, the essential and particular function of the autonomic system is to contribute to the

internal adjustments upon which this constant state depends

The great majority of the effector organs of the autonomic system are innervated by both sympathetic and parasympathetic divisions, and the effects exerted by the two types of fiber going to a given organ are antagonistic Thus, the heart's action is inhibited by the vagus but augmented by the sympathetic In the intestine the effects of the two systems are reversed, the parasympathetic (vagus nerve to the small bowel and upper half of the colon, and the pelvic nerve to the lower half of the latter) is augmentative, the sympathetic is inhibitory The removal of the effects of one set of fibers, as by section, results, as a rule, in the effects of the other set becoming more prominent, at least temporarily This fact indicates that each type of fiber exerts a constant or tonic action and suggests that the two effects are delicately balanced one against the other Thus, section of the vagus nerves causes an increase in the cardiac rate, and section of the parasympathetic or of the sympathetic fibers to the iris causes, respectively, dilation or constriction of the pupil

Taken as a whole the actions of the sympathetic division including the medulla of the adrenal gland are directed towards strengthening an animal's defenses against the various dangers which beset it, e g , extremes of temperature, deprivation of water, or the attacks of its enemies It has been shown by Cannon et al (1929), however, that the sympathetic system is not indispensable, both ganglıated cords may be completely removed yet the animal remains in good health provided it is kept in the sheltered environment of the laboratory Sympathectomized cats if kept warm and carefully tended will live indefinitely Kittens deprived of their sympathetic trunks grow normally, female cats become pregnant and give birth to young, though the mammary glands do not function normally because of interruption of the sensory nerves supplying the nipples Sympathectomized animals are, however, incapable of arduous work, sugar is not mobilized from the liver on demand, an increase of circulating red blood cells does not occur during excitement or exercise, the usual reactions to cold (elevation of the hairs and vasoconstriction) fail, and epinephrine is not liberated in an emergency They are also less able to withstand oxygen lack or hemorrhage than are normal animals It is evident that the sympathectomized animal could not fend for itself, and, in the struggle for existence, would soon succumb to the hazards of the environment The sympathetic ganglionated chain has also been completely removed in man, thus abolishing all connection of the peripheral sympathetic system with the central nervous system, without producing any serious consequences

Parasympathetic effects, as noted above, are more localized in character It has also been suggested that they are concerned with conservative and restorative processes, in contrast to the sympathetic with processes involving the expenditure of energy Inhibition of the heart, contraction of the pupil for the protection of the eye from intense light and the activities of the digestive tract, through which the energy stores of the body are replenished, are frequently given as examples of acts of conservation presided over by the parasympathetic These apparent differences in the activities of the two divisions have led some (following Gaskell) to speak of the functions of the sympathetic and parasympathetic divisions as *catabolic* and *anabolic*, respectively It is an interesting but essentially a philosophical generalization

Chemical (Humoral) Transmission of Nervous Impulses

In the autonomic nervous system the transmission of impulses from neuron to neuron, and from neuron to effector cell is accomplished by the elaboration of chemical substances by the nerves (sect 1, chap 3) The classical experiments of Otto Loewi, in 1921, first clearly demonstrated the existence of humoral mediators Two frog hearts, arranged in standard fashion for recording contractions, were prepared so that the fluid perfusing one heart could come in contact with the second Upon stimulation of the vagus nerve to the first heart, its rate of contraction was reduced When the fluid perfusing this heart came in contact with the second it also slowed in rate although its vagus had not been stimulated Some substance had obviously been released in the first heart which could be carried by the perfusing fluid to the second Loewi termed this material *Vagusstuffe* By the same technique, stimulation of the cardiac accelerator nerve to the first heart increased its rate and

also the rate of the second heart when the perfusing fluid reached the latter This response Loewi attributed to the release of *Acceleranss-tuffe*

By various techniques, *Vagusstuffe* has been shown to be acetylcholine, and *Acceleranss-tuffe* is norepinephrine In 1933, Sir Henry Dale proposed the terms *cholinergic* and *adrenergic* to describe the nerves which liberated acetylcholine or epinephrine (or related substances) (Fig 9 47) The adjectives are also used to describe agents which cause effects similar to those produced by acetylcholine and epinephrine Dale also proposed that cells stimulated by cholinergic or adrenergic nerves be termed cholinoceptive and adrenoceptive, respectively

CHOLINERGIC TRANSMISSION

Acetylcholine is now recognized as the mediator of impulses at all autonomic ganglia, in the adrenal medulla, at all parasympathetic

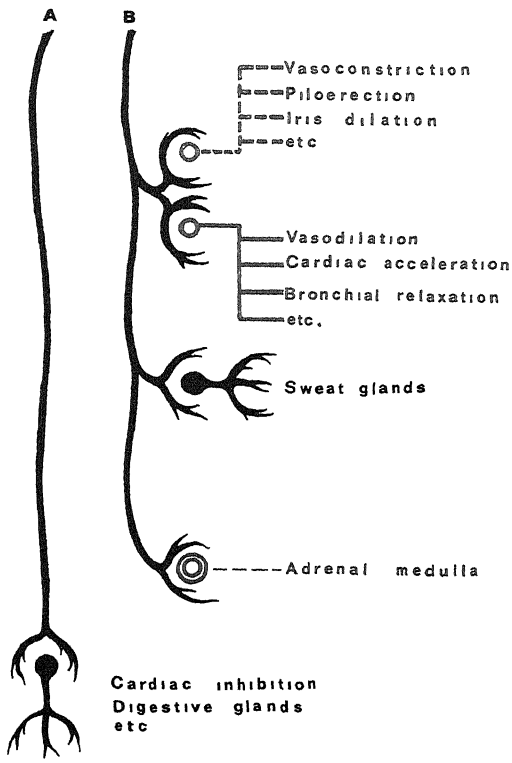

Fig 9 47 Distribution of cholinergic and adrenergic fibers in parasympathetic (*left*) and sympathetic divisions of the autonomic system Cholinergic mechanisms are in black adrenergic neurons are in color

postganglionic terminations, sympathetic postganglionic endings at sweat glands, and motor nerve endings at skeletal muscle In these cholinergic nerve fibers acetylcholine is synthesized (Ritchie and Goldberg, 1970), and retained in an inactive form in morphologically discrete vesicles Upon stimulation of the nerve the acetylcholine is set free and diffuses from the terminations (Paton et al , 1971) The same vesicles contain an enzyme, cholinacetylase, which promotes the synthesis of acetylcholine from choline and acetyl coenzyme A Cholinacetylase is very widely distributed in the nervous tissues, being found in brain, ganglia, and peripheral nerves, it is also present in the placenta, but is absent from liver and kidney For optimal activity this enzyme requires Mg^{++}, K^{+} and Ca^{++} ions (Fig 9 48)

Transmission of excitation from one neuron to another is accomplished by the release of acetylcholine from these synaptic vesicles into the "cleft" between the terminals of the first neuron and the receptor mechanism of the second Calcium ions are required for this release of acetylcholine Fatt and Katz (1952) demonstrated that the presynaptic transmission process is not infinitely graded, but exhibits discrete increments that depend upon the release of acetylcholine molecules in bursts of several thousand molecules each (Fig 9 13, p 9-13) They correlated postsynaptic endplate potentials with the release of these packets or quanta of transmitter molecules

The action of this acetylcholine upon the postsynaptic cell is compatible with the hypothesis that it combines with a receptor substance in the membrane under the presynaptic termina The receptor is believed to be limited to the exterior of the membrane, because Del Castillo and Katz (1955) found that intracellular injection of acetylcholine did not activate the postsynaptic cell Ordinarily the receptor is found only adjacent to the terminal If the presynaptic nerve fiber is cut, however, after some days the postsynaptic cell seems to become hypersensitive to the transmitter substance—in this instance, to acetylcholine When this occurs the area of the membrane sensitive to acetylcholine spreads from the region of the terminals until the entire surface of the muscle cell becomes sensitive With reinnervation, the receptive surface contracts until it is once again limited to the area under the

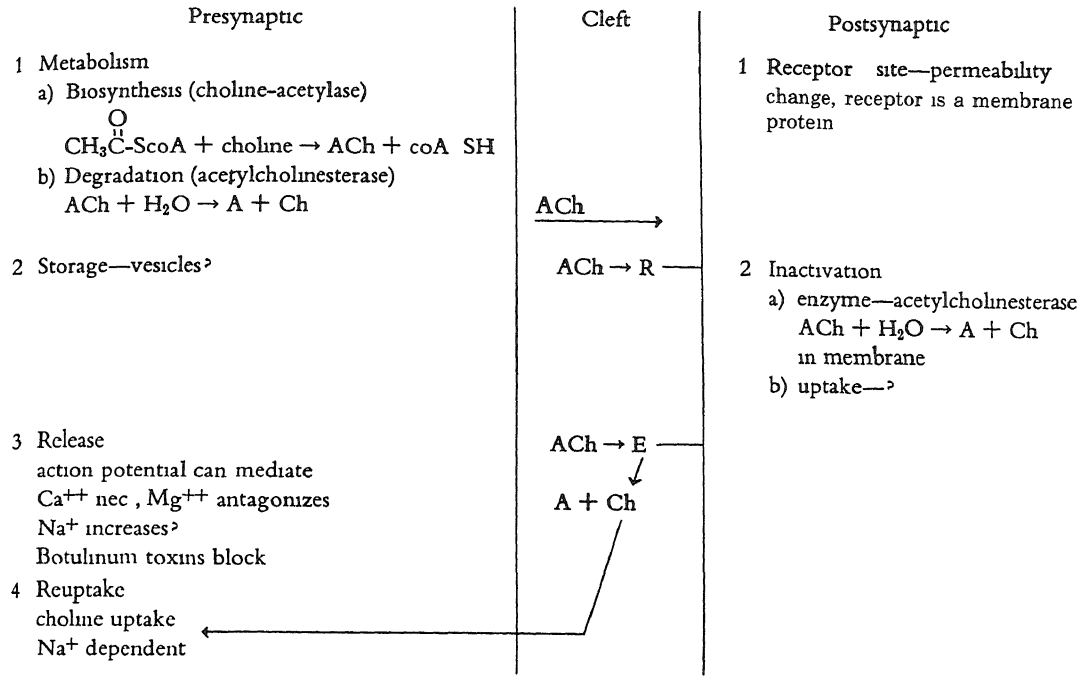

Fig 9 48 Synaptic chemistry of acetylcholine (Kravitz 1967)

terminals (Miledi, 1960) The nature and identity of the receptor substance are unknown

After its release acetylcholine is unstable, it is readily hydrolyzed to choline and acetate ion This hydrolysis occurs almost instantaneously in the presence of *acetylcholinesterase*, an enzyme present at the termination of cholinergic nerves The enzyme is one of a group of hydrolytic enzymes, often referred to as cholinesterases, found in the body Acetylcholinesterase, or *true* or *specific cholinesterase*, has acetylcholine as its preferred or only substrate, and is most effective when the amount of acetylcholine is small The other (pseudo- or nonspecific) cholinesterases will utilize acetylcholine and other choline and noncholine esters as a substrate and are most effective in the presence of large quantities of acetylcholine

Cholinesterases may be inhibited by a variety of substances Much of the knowledge about acetylcholine and nerve impulse transmission has been obtained through the ability of these agents to inhibit acetylcholinesterase Physostigmine (eserine), an alkaloid extracted from the Calabar bean (*Physostigma venenosum*) was the first substance shown to inhibit these enzymes Subsequently many synthetic inhibitors have been prepared, among them neostigmine (Prostigmin), di-isopropylfluorophosphate (DFP) and tetraethylpyrophosphate (TEPP) Physostigmine and neostigmine are reversible inhibitors, the enzyme is inactivated only so long as it is in combination with the inhibitor As the latter is eliminated by the body, the enzyme once more becomes active DFP and TEPP combine irreversibly with the enzyme, permanently inactivating it Hence, for cholinesterase activity to be restored new enzyme must be synthesized

Acetylcholine Liberation during the Discharge of Epinephrine. Stimulation of the sympathetic fibers supplying the adrenal medulla causes an acetylcholine-like substance to appear in the blood of the adrenal vein It has therefore been concluded that acetylcholine acts as a chemical transmitter from the nerve terminals to the medullary cells It will be recalled that the sympathetic fibers ending in the adrenal are preganglionic, the adrenal cell being in fact a postganglionic neuron

Acetylcholine as the Transmitter of

Effects to the Sweat Glands. Although the human sweat glands are innervated by the sympathetic, their behavior to drugs is similar to that of structures supplied by the parasympathetic, they are unaffected by epinephrine, stimulated by pilocarpine, and paralyzed by atropine Dale and Feldberg (1934) showed that excitation of the sympathetic fibers to the foot pads of the cat is followed by sweating and the appearance of acetylcholine in the eserinized fluid perfusing the paw

ADRENERGIC TRANSMISSION

Knowledge of the chemistry of the adrenergic mediator has increased dramatically in recent years Cannon and Bacq in 1931 demonstrated that stimulation of adrenergic nerves liberates into the circulation a substance which they called "sympathin " Although many of the effects of sympathetic stimulation could be reproduced by administration of epinephrine, Cannon and Rosenblueth (1933) were unable to demonstrate a complete qualitative and quantitative identity between the two types of stimulation U S von Euler (1946) then showed that "sympathin" is a compound related to *epinephrine*, namely, dl-(3,4-dihydroxyphenyl) ethanolamine or *norepinephrine*

The confusion arising from much of the original work with the adrenergic mediators was related to the difficulty in separating epinephrine and norepinephrine, and correctly identifying these compounds For example, extracts of the adrenal medulla contain roughly 10% of norepinephrine as a contaminant of what was believed to be pure epinephrine On the other hand, norepinephrine is the principal if not the only chemical mediator at adrenergic postganglionic sympathetic nerve endings (see von Euler, 1971)

Epinephrine and norepinephrine belong to a class of compounds known as catecholamines, synthesized in the body from phenylalanine The series includes a precursor, (3,4-dihydroxyphenyl) alanine (dopa), (3,4-dihydroxyphenyl) ethyl amine ("dopamine"), (3,4-dihydroxyphenyl) ethanolamine (norepinephrine, arterenol); methyl norepinephrine (epinephrine), and another compound known as isopropylarterenol or isoproterenol (see Fig 9 49) These compounds have been studied intensively, so that their pathways of synthesis are largely known, and also the reactions through

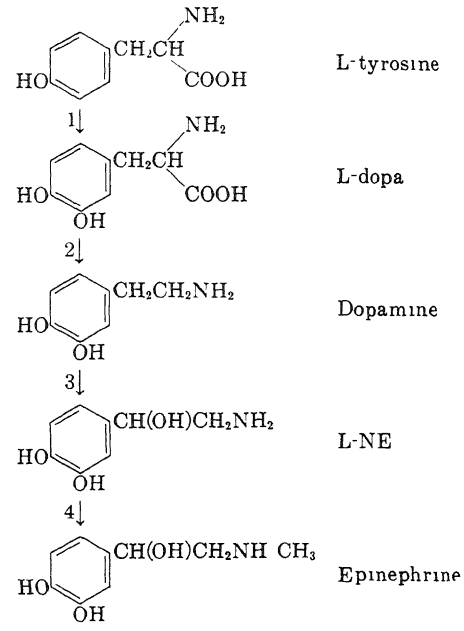

Fig 9 49 Biosynthesis of catecholamines from L-tyrosine (i e hydroxyphenylalanine) The enzyme for the fourth step phenylethanolamine *N*-methyl transferase is present in adrenal medulla and chromaffin tissues but not in typical postganglionic adrenergic endings (Iversen 1967)

which they are inactivated in biological systems (Iversen, 1967)

The synthesis of the adrenergic mediators from phenylalanine can proceed through a variety of pathways There are vesicles present in adrenergic nerve terminations which apparently subserve the function of storage of norepinephrine (Geffen and Livett, 1971), and which contain the enzyme, *dopamine-β-oxidase*, which converts dopamine to norepinephrine. Nerve terminals have an interesting mechanism for conserving norepinephrine, inasmuch as most of the norepinephrine present in these vesicles comes from that which was liberated by the nerve ending, the substance diffusing back into the nerve, and thence into the vesicles (Fig 9 50) Stromblad and Nickerson (1961) demonstrated that both epinephrine and norepinephrine, exogenously administered, could be stored in the tissues, and that the storage was less in chronic sympathetically denervated tissues, suggesting that the site of storage was in the nerve endings

The concept of the mobility of the adre-

nergic mediator out of, and back into, the nerve endings is important for an understanding of various drug effects and the duration of the effects of adrenergic nerve stimulation For, compared to acetylcholine, the adrenergic mediators are inactivated relatively slowly

Inactivation. At least four possible pathways of epinephrine metabolism have been described *1*) An enzyme, *monoamine oxidase*, is present throughout the body which is capable of oxidatively deaminating primary amines Epinephrine and norepinephrine are substrates for this enzyme, although the reaction proceeds rather slowly *2*) Conjugation of epinephrine with glucuronic or sulfuric acid at the hydroxyl groups occurs, primarily in the liver and intestines *3*) The phenolic hydroxyl groups of epinephrine are readily oxidized, forming a quinone which in turn forms a cyclic structure *adrenochrome* *4*) Axelrod (see Axelrod and Kopin, 1969) has demonstrated that the phenolic group in the *meta* position is methylated by the enzyme, O-methyltransferase, in the body (Fig 9 51) This probably is the principal metabolic pathway for circulating epinephrine and norepinephrine It appears, however, that none of these inactivating mechanisms is the one primarily responsible for terminating adrenergic effects Rather, the termination of adrenergic effects results from the diffusion of the mediator from the effector site back into the nerve termination

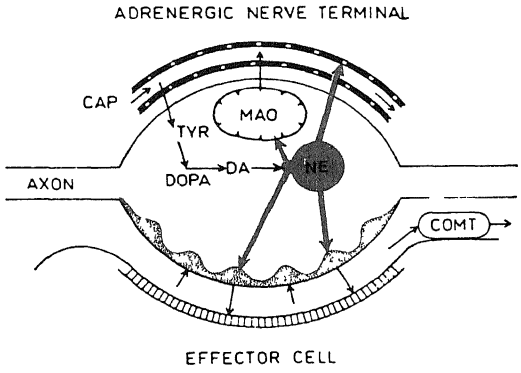

Fig 9 50 Schematic drawing of adrenergic nerve terminal Pathway of synthesis of norepinephrine (*NE*) from tyrosine (*TYR*) is shown together with presence of monoamine oxidase (*MAO*) Norepinephrine is released from storage sites and also re-accumulated into these sites some is oxidized by catechol-*O*-methyl transferase (von Euler 1971)

Receptor Sites The concept of specific receptors, first proposed by Dale in 1906, aids in understanding the rather complex responses to sympathetic stimulation or epinephrine administration Noting that epinephrine caused some smooth muscle to contract, while it relaxed others, he proposed that the former had "motor" type receptors while the latter had "inhibitory" type receptors In 1948 an American pharmacologist, Ahlquist, proposed a modification of this concept that is now universally accepted He utilized five different catecholamines, including epinephrine, norepinephrine, and isoproteranol, in a comparative test of their potency on a variety of physiological reactions He found that these amines had one rank order of potency in evoking vasoconstriction, excitation of uterus and ureters, contraction of nictitating membrane, dilatation of pupil and inhibition of smooth muscle in the intestine But they had a different rank order of potency when tested on functions that included vasodilatation, inhibition of the uterus, and myocardial stimulation From these results he concluded that the effector cells must

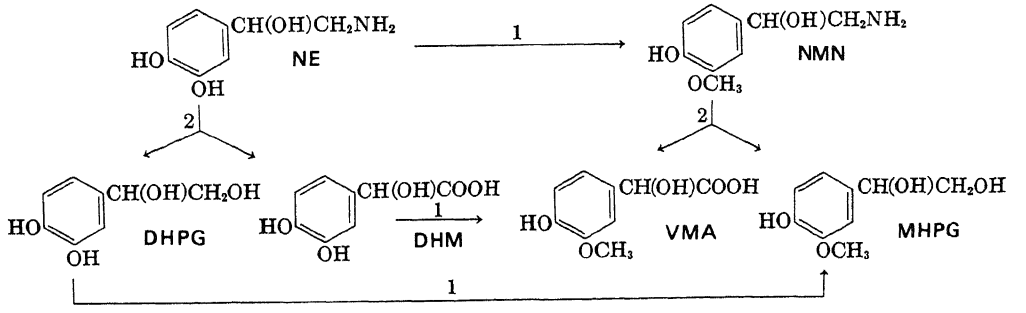

Fig 9 51 Pathways by which catecholamines are inactivated by catechol-*O*-methyl transferase (1) or by monoamine oxidase (2) *NE* is norepinephrine *NMN* is normetanephrine *DHPG* is 3,4-dihydroxyphenylethylglycol DHM is 3 4-dihydroxymandelic acid *MHPG* is 3-methoxy 4-hydroxyphenylethylglycol *VMA* is 3-methoxy, 4-hydroxymandelic acid (Iversen, 1967)

possess two different types of adrenergic receptor mechanisms, one of which is associated with most of the excitatory functions and inhibition of smooth muscle of the intestine The other is associated with most of the inhibitory functions plus an excitatory action upon the heart These hypothetical receptors, given the designation α and β, have been extensively studied by later investigators, with the general conclusions shown in Table 9 2 Furchgott (1954) has presented evidence which indicates that with vascular smooth muscle, at least, individual cells may contain both α and β *receptors*

Norepinephrine appears to stimulate only α-receptors, isoproterenol only β-receptors, and epinephrine is capable of stimulating both Epinephrine is 2 to 10 times more potent than norepinephrine in stimulating the α receptors Isoproterenol is 2 to 10 times more potent than epinephrine in stimulating the β receptors and 100 or more times more active than norepinephrine Therefore, although epinephrine is the more potent agent as a vasoconstrictor, norepinephrine may produce a greater rise in blood pressure for a given dose, since it has little or no effect on vasodilator fibers

Table 9 2
Functions of α and β adrenergic receptors

α Receptors
Vasoconstriction, especially in vessels of skin, mucosa, gut, salivary glands, lungs, cerebral circulation
Stimulation of contraction of radial muscle of iris (pupillodilation), of nictitating membrane, of pilomotor muscles, of muscle of uterus, and of ureter
Stimulation of glycogenolysis
Inhibition of insulin secretion
Inhibition of smooth muscle of intestine
β Receptors
Vasodilatation in coronary circulation and in skeletal muscle, and possibly in the liver
Relaxation of muscle of bronchi, and of uterus
Stimulation of lipolysis
Stimulation of insulin secretion
Stimulation of heart, with cardioacceleration, increase in contractility of muscle of atria and ventricles

Higher Levels of Visceral Control Systems

Both afferent and efferent components of the visceral control systems can be demonstrated in levels above the segmental or reflex mechanisms of spinal cord and cranial nerves The cell bodies of the interneuronal (preganglionic) neurons lie in a column of cells that is continuous throughout thoracic and lumbar segments of the cord, can be identified but is less conspicuous in sacral segments, and is grossly interrupted in the brainstem where it has the form of four isolated cell groups (see preceding chapter) In the spinal cord it is called the intermediolateral cell column of the central grey substance, because of its location and relationships, in the brainstem each of the four cell groups is designated as a "nucleus"—the Edinger-Westphal nucleus of nerve III, the salivatory nuclei of nerves VII, and IX, and the dorsal motor nucleus of the vagus (nerve X)

If there is any processing of information, or modulation of control, within autonomic ganglia it is of only a simple nature, and can involve only the terminations of preganglionic upon postganglionic neurons, inasmuch as afferent fibers do not send terminals to cells in the ganglia Synaptic functions within ganglia seem to be stereotyped A functional significance is attributed, however, to the difference in innervation ratios in the two divisions of the autonomic motor system In the craniosacral portion each preganglionic neuron innervates only a limited number of postganglionic cells, and control tends to be discrete rather than diffuse In the thoracolumbar portion, by contrast, fibers from white rami may terminate in a given ganglion, or also run through it or even through several ganglia, with terminations upon as many as 30 postganglionic cells This means that responses tend to be diffuse or generalized This tendency is reinforced by the circumstance that one of the principal collections of thoracolumbar postganglionic cells is the medulla of the adrenal gland By discharging their "transmitter," which is epinephrine with smaller percentage of norepinephrine, directly into the circulation they assure the generalized character of any significant sympathetic activation

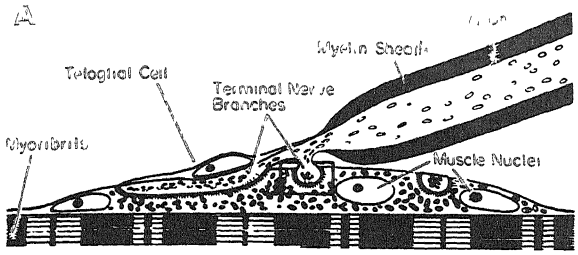
A lack of data regarding what happens in the intermediolateral cell column makes it impossible to discuss the nature of control at this level On the other hand, there are plentiful data regarding stimulation of autonomic

otor systems both directly and reflexly thin brainstem, diencephalon, and even cerellum and cerebral cortex Neurons that can activated at these levels must be regarded connector, internuncial neurons, but they e also computational in that they are responle for naturally occurring control responses ie earliest experiments upon these higher echanisms were intended to disclose the lotion of a mechanism that produces glycosa after surgical injury to the medulla oblonta, the *sucre piqûre* of Claude Bernard They l to the concept that the medulla contains a eflex" center for control of epinephrine setion In later experiments electrical stimuion of the floor of the 4th ventricle was ind to produce a rise in blood pressure, aceration of the heart, peripheral vasoconiction, and secretion of epinephrine, and it came clear that autonomic controls are jor functions of the brainstem These sysns are now classified as the so-called medully cardiac center, vasopressor center, or vasepressor center (please see sect 8, chaps ind 9) Similar studies related to control of lmonary ventilation involve "automatic" ; not autonomic mechanisms, as discussed section 6, chapter 4

Just before the first World War, two Viense investigators, Karplus and Kreidl (1910), covered that they could evoke a surprising riety of sympathetic responses by stimuing the base of the brain in animals where y had exposed the brain by removal of one it Ranson (1936, 1937) and his associates er repeated their experiments with the preion of the sterotaxic method, and described inges in heart rate, blood pressure, respiran, secretion of salivary and other glands, as ll as changes in the motility of stomach, vel, and bladder after stimulation within hypothalamus The most active sites were the lateral hypothalamus, and some of the ponses obtained were in the nature of inhiion rather than stimulation (Ingram, 1939) m their results and those of other laboratos came almost innumerable attempts to asn the several portions of the hypothalamus either the craniosacral or thoracolumbar systems Many authors have concluded that the rostral hypothalamus tends to be craniosacral in its orientation, with the more caudal part thoracolumbar As a generalization, however, it is more nearly correct to say that the lateral hypothalamus tends to be excitatory and the medial hypothalamus inhibitory, no matter what kind of control system is under consideration Moreover, from an electrode at any given locus in the hypothalamus one may obtain either a rise or a fall in blood pressure and heart rate, depending upon the frequency and strength of the electrical stimulation These observations, together with the disclosure that the hypothalamus participates in predictable ways in control systems having obvious functions suggests that the goal of identifying discrete "centers" for sympathetic as opposed to parasympathetic actions is not in keeping with the organization of this portion of the brain

Although the hypothalamus is sometimes said to be the level of highest control of autonomic functions, the "head ganglion" of the autonomic system, it is not the highest level from which autonomic responses can be evoked There are reports of alterations in blood pressure and heart rate, as well as in peripheral distribution of blood flow, following stimulation of certain regions of the cerebral cortex, and even after cerebellar stimulation Neither the nature of the responses nor the location of the active sites lends itself to any generalization as to the significance of these results One possibility is that, inasmuch as Pavlovian conditioning in general requires cortical function, and inasmuch as autonomic responses readily show conditioning, this may be the significance of these cerebral locations One cannot say, however, whether any particular lesion or ablation of the cerebral cortex will reduce or abolish any one of these conditioned responses Another interesting possibility has followed the discovery that many of the regions from which autonomic responses can be evoked belong to what is known as the "limbic system" (MacLean, 1970), the portion of the brain believed to be responsible for emotional experience (chap 8, p 9-156)

4 / CONTROL OF SKELETAL MUSCLE



The process that ultimately evokes shortening of skeletal muscle via the actomyosin complex is believed to be a release of calcium ions from the membrane of the muscle fiber In mammalian striated muscles this calcium is stored in what is known as the *triad*, a structure adjacent to the transverse (or T) tubules of the sarcoplasmic reticulum, and also adjacent to the cisternae that run parallel to the fibrils The lumen of the transverse tubule is continuous with the extracellular compartment surrounding the muscle cell, and the membrane lining the tubule is likewise a projection of the sarcolemmal membrane When microelectrodes are placed on the sarcolemmal membrane in the region of origin of a transverse tubule, the application of an electrical stimulus produces a contraction of only the two adjacent half-sarcomeres on each side of the tubule (Huxley and Straub, 1958, Huxley and Taylor, 1958) Apparently the excitatory process initiated in the sarcolemma is propagated into the muscle via the transverse tubule, where it brings about a release of calcium ions from the triad, and hence the initiation of the contraction process (see Peachey, 1965, Winegrad, 1965)

If the ultimate process is taken to lie in the triad and sarcoplasmic reticulum, at least two other stages of excitation and transmission are interposed between this final level and the nerve impulse of a motor nerve Just above the level of the reticulum is the membrane of the muscle cell It is this membrane that may or may not be activated by natural or artificial stimulation It is also this membrane that gives the contraction process some of its classic characteristics, including the all-or-nothing phenomenon The membrane may undergo local changes that electrically have the characteristics of electrotonus, the local excitatory state (LES) described in chapter 1 When this local state becomes intense enough in a short enough time course, a disturbance analogous to a nerve impulse is spread over the surface of the fiber, and throughout its sarcoplasmic reticulum

At the next higher level of control is the nerve ending on the muscle, which typically has the form of a motor end-plate (Fig 9 52) The nerve impulse reaches the ending, and there sets up processes similar to those responsible for synaptic transmission in autonomic ganglia The onset and course of these processes may be followed by recording of potential changes, but the processes per se are physicochemical, and involve the release of acetylcholine from vesicles in the nerve ending, the diffusion of the acetylcholine across the neuromuscular "cleft," and some unknown interaction of the acetylcholine with a receptor substance present on the sarcolemmal membrane only in the region of the motor end-plate The acetylcholine so released is inactivated almost at once by acetylcholinesterase, but if the quantity of acetylcholine released and the time course of its release were adequate, the combination of the transmitter and the receptor substance alters the membrane potential of the sarcolemma sufficient to initiate the wave of excitation noted above The electrical sign of this excitation is a reversal in polarity of the muscle's membrane potential, As in nerve, this *action potential* is not identical with the wave of excitation that induces it, but the more fundamental reaction known as a *nerve impulse* in nerve has no comparable brief name when it occurs in muscle

Central Neural Control of Muscle

All striated or skeletal muscles of higher animals are controlled by neurons located in the motor columns of spinal cord and brainstem, that send their axons to the periphery in spinal or cranial nerves In the spinal cord these neurons are collected in the anterior grey columns into groups innervating the individual muscles or muscle groups (chap 1) In the brainstem they are present in two distinct columns One innervates muscles derived embryologically from myotomes, and includes the motor nuclei of the oculomotor, trochlear, abducens, and hypoglossal nerves The other innervates striated muscles derived from the

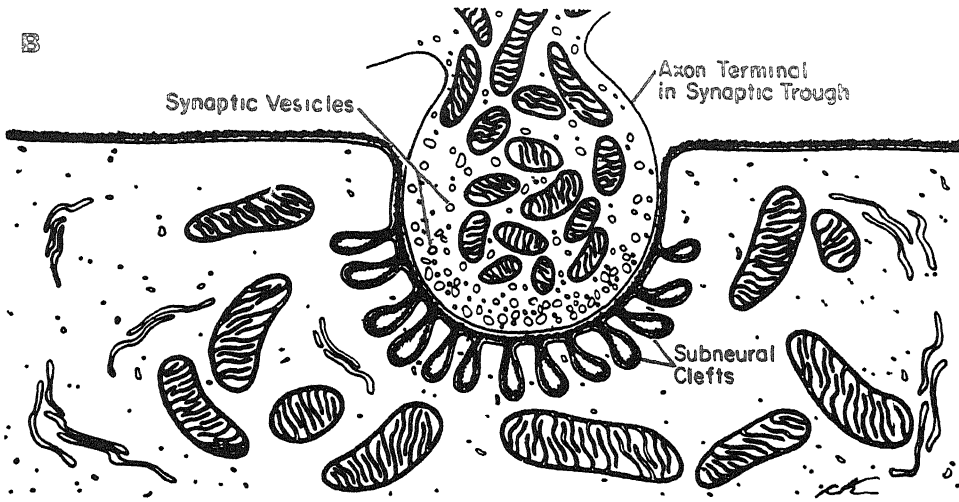


Fig 9 52 Motor end plate for neuromuscular transmission in striated muscle *A* Diagram of microscopic appearance *B* diagram based on electronmicroscopic data (Bloom and Fawcett 1968)

embryonic branchial arches, and includes motor nuclei of the trigeminal and facial nerves, in addition to the nucleus ambiguus that gives rise to motor fibers in the glossopharyngeal, vagus, and accessory nerves to supply striated muscles of the pharynx and larynx

It is not possible to describe the control of skeletal muscle by considering only the motor neurons They are continuously under the influence of other neurons, including mainly the afferent (receptor) neurons and the connector (internuncial) neurons of that level of the neuroaxis They are also affected by nerve impulses that come from the opposite side of the spinal cord or brain, and by impulses from lower and especially from higher mechanisms In spite of this complexity, many of the properties of the motor control systems can be disclosed by study of the segmental mechanisms responsible for what is known as *reflex action*

CHARACTERISTICS OF REFLEX ACTIVITY

The anatomical basis of reflex action is the reflex arc (Fig 9 53), which has three basic components *a*) An afferent limb is composed of the receptor organ, which upon excitation, gives rise to nerve impulses and the neuron whose processes transmit the impulse to the central nervous system, it may consist of the spinal reflex arc, the cell bodies of the afferent neurons are situated in the posterior root ganglia *b*) An efferent limb is constituted of a motor neuron which conducts impulses from the central nervous system to an effector organ-muscle or gland In the case of motor spinal reflex arcs, the axons of the efferent neurons leave the cord by the anterior nerve roots and travel in the peripheral nerves, their cell bodies are situated in the anterior horns *c*) A "center" is situated in the gray matter of the central nervous system, it may consist of the cell body and dendrites of the efferent neuron

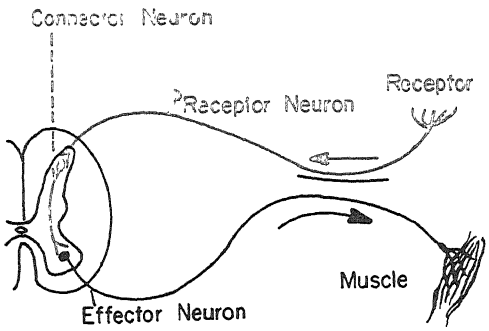

Fig 9 53 Diagram of a simple reflex arc

and its junction (synapse) with the central process of the afferent neuron

The afferent and efferent limbs may connect directly in the center, but usually one or more nerve cells may be interposed between the two These are spoken of as connector, internuncial, or intercalated neurons (Fig 9 53) The stretch reflex as shown by Lloyd (1943, 1944) can be carried out through a reflex arc of only two neurons, but the great majority of the spinal reflex arcs in higher animals consist of several neurons, and in most reflexes each afferent neuron makes connection through collateral branches and internuncial neurons with a large number of motoneurons

Injury, leading to loss of function of any one part of the reflex arc, is sufficient to alter the function of the whole

The scientific study of reflexes may be said to have begun early in the 1800's when Bell (1811) in England and Magendie (1822a and b) in France established the functions of the dorsal and ventral roots of the spinal cord (see Fulton and Wilson, 1966) By the beginning of the present century, Sherrington (1906) at London, Liverpool, and then at Oxford had begun a detailed, quantitative investigation of the properties of extensor and flexor reflexes At about the same time the Spanish anatomist, Ramón y Cajal (1909, 1911) presented histological evidence in support of the neuron "doctrine," asserting that sensory and motor neurons are contiguous but not continuous But neurophysiological investigations of reflex activity did not penetrate to the synaptic level until the introduction of electrophysiological methods The use of such methods was pioneered in the years 1920 to 1926 by Erlanger and Gasser (see 1937), who made extensive employment of the cathode ray oscilloscope for study of electrical responses of nerve and spinal cord

At this time electrophysiological methods were also introduced by Adrian (see 1935) for the investigation of receptor responses With Bronk (Adrian and Bronk, 1929), he carried out one of the most important of the early studies of how information is coded in sensory nerves Some years later the introduction of glass microelectrodes by Ling and Gerard (1949) enabled workers such as Eccles (1953) to examine the events of excitation and inhibition at the neuronal level in the spinal cord

Classification of Reflexes. Reflexes may be classified as segmental, intersegmental, and suprasegmental on the basis of their connections in the spinal cord Those reflexes whose arcs pass through only one segment of the spinal cord include, for example, the patellar reflex or knee jerk Intersegmental reflexes involve ascending or descending pathways, thus, pinching the hind limb of a cat may lead to flexion of a contralateral forelimb Suprasegmental reflexes involve interactions between nuclei above the cord and the segments of the cord itself Such reflexes are exemplified by movements of the head causing extension of the limbs in a spinal animal The principal reflexes utilized for investigating the properties of the synapse have been the segmental

Another classification of reflexes has proved useful in clinical work Reflexes are classified into four categories superficial, deep, visceral, and pathological Superficial reflexes are those elicited from mucous membranes or skin, i e, the surface of the body Examples of such reflexes are the corneal reflex, or blinking of the eye when the cornea is touched, and the plantar reflex, a flexion of the toes when the sole of the foot is stroked Deep reflexes are stretch reflexes in which extension of a muscle is obtained by striking the tendon of a given muscle The patellar reflex (knee jerk), triceps and biceps reflexes are examples of this type of reflex Visceral reflexes are elicited from deep-lying structures examples of such reflexes are the pupillary reflex, i e, constriction of the pupil when light is shined in the eye, and the carotid sinus reflex, in which pressure on the carotid sinus causes a fall in blood pressure Finally, the pathological reflexes consist of those which are present only as an abnormality An example of this type is the Babinski reflex which consists of a spreading of

the toes when the plantar surface of the foot is stroked This reflex may be evoked from humans when injuries to the upper motor pathways of the spinal cord are present

The Reflex Preparation. Two animal preparations have usually been employed to study the properties of spinal reflexes, the spinal and the decerebrate animal The *spinal animal* is prepared by sectioning the cord at any level above the level to be studied If the section is higher than the lower cervical region, artificial respiration is necessary because the motor neurons of the phrenic nerve are cut off from necessary medullary control (sect 6, chap 4) Immediately after the transection, the spinal animal is in a condition called *spinal shock* in which there is complete absence of reflexes below the level of the section Within an hour or two there is a return of the flexion and extension reflexes in the cat and dog, in the human the return may take weeks or more The blood pressure of the spinal animal tends to fall immediately after the section, but if the animal is properly maintained, oxygenation is satisfactory, acid-base balance of the blood is achieved, and the blood pressure returns to normal values

A *decerebrate* animal is prepared by transecting the brainstem through the mesencephalon, usually at a level between superior and inferior colliculi As soon as it recovers from the anesthetic used during the operation, such an animal shows striking exaggeration of stretch reflexes, particularly in extensor and other "antigravity" muscles The limbs are rigid, with hyperextension of the back (opisthotonus) and tail, and tight closure of the jaws The usefulness of either a spinal or a decerebrate preparation is that it permits the study of reflexes without anesthesia that would depress reflex activity Furthermore, by comparing the two types of preparation one can learn something about functional levels in the spinal cord and brainstem, especially when sections are made at varied levels in the spinal cord, and at different levels through the brainstem

Sherrington (1906) studied mainly the spinal reflexes of muscles acting upon the lower limbs of cats (Table 9 3) The lower the plane of the section through the spinal cord the more easily the preparation can be maintained for study His usual procedure involved the following steps general anesthesia using ether, decerebration followed by withdrawal of the anesthesia, exposure of the lower thoracic spinal cord, followed by transection of the cord, exposure of sacral cord, with transection In this

Table 9 3

Typical reflex responses of a dog or cat with a section of the central neural axis classified by level and stage of recovery for flexor and extensor muscles

Operation	Flexor Muscles	Extensor Muscles
Low spinal section i e , transection at or about level of last rib		
i) "Acute spinal," i e , some minutes or hours after transection	Flexor reflex easily evoked Tendon-jerk present ('pluck reflex') Crossed inhibition	Tendon-jerk present
ii) "Chronic spinal" i e , some days, weeks, or months after transection	Flexor reflex easily evoked Tendon-jerk present Crossed inhibition	Tendon-jerk present Imperfect stretch reflex (postural) Extensor thrust Crossed extensor reflex
Decerebrate i e , transection between anterior and posterior colliculi some minutes or hours previously	Flexor reflex less readily evoked, but once evoked has considerable after-discharge Tendon-jerk Crossed inhibition	Tendon-jerk with marked tonic after-discharge Stretch reflex exaggerated and chief factor in decerebrate rigidity Crossed extensor reflex easily obtained with long tonic after-discharge

Creed et al , 1932

fashion the lumbar elargement of the cord, the site of reflex connections for the lower limbs, was left in situ but deprived of influences from both higher and lower levels The decerebration permitted study of the animal without pain even in the absence of anesthesia

The activity of spinal motor neurons was displayed by using a muscle as an indicator The tendon of the muscle was attached to a torsion wire myograph, with a pointer writing upon the smoked drum of a kymograph Other muscles that might pull upon the myograph were either denervated or sectioned

Types of Reflex Studied. Many experiments involved the *flexion reflex*, by definition a reflex contraction of a flexor muscle such as tibialis anticus This is the reflex that withdraws the foot when an animal steps upon a sharp or hot surface It includes contraction of the appropriate flexor muscles, inhibition of the opposing extensor muscles of that limb, activation of extensor muscles of the opposite limb, and changes in tone of muscles in the other two limbs as adjustments to the altered center of gravity of the body

In other experiments the *stretch reflex* was analyzed Its latency is so short that Sherrington at first was not certain it was a true reflex It is a quick, brief, and sometimes powerful contraction to a sharp stretch of a muscle and its tendon, and includes the knee jerk, ankle jerk, biceps or triceps jerk as examples It may be, however, a more prolonged contraction following a continued stretching of the muscle, especially in the case of an extensor muscle in a decerebrate preparation

Although the terms are sometimes confused, it is important to understand that the flexor reflex and stretch reflex are not opposites of one another For example, both flexor and extensor muscles may exhibit stretch reflexes, as do the biceps and triceps muscles in the arm The fact that flexion reflexes are necessarily studied in flexor muscles, while stretch reflexes have been studied mainly in extensor muscles, is responsible for the confusion Flexion and stretch reflexes may be compared or contrasted, but one should not regard the latter as necessarily an extensor reflex

Stimulation used to evoke a flexor reflex is usually an alternating electrical current applied to a cutaneous, sensory nerve More natural stimuli such as pinching of a toe pad, or any other usually painful procedure may be utilized For stretch reflexes the muscle is pulled, briefly for a *phasic* response or continuously for a *static* response Sherrington fastened one end of the muscle to the myograph and then let the table carrying the animal fall away from it (see Creed et al , 1932) A more modern device has the animal in a fixed position on a table that can be elevated by means of a lever and cam, so that the muscle pulls upon a strain guage

FLEXION REFLEX

The significance of Sherrington's study of flexion reflexes (see Sherrington, 1906, Creed et al , 1932) lies not so much in what it revealed as to the character of the reflex response, but rather in the insight he provided into the nature of mechanisms lying within the spinal cord The reflex, itself, has the following characteristics

1) From a muscle such as tibialis anticus in cat, a flexor of the ankle, a reflex contraction can be elicited following stimulation of any of the cutaneous nerves of that leg

2) A stimulus in the form of a single shock gives a single twitch of the muscle

3) Repeated stimulation may give a reflex tetanus.

4) The magnitude of the responses obtained from the several cutaneous nerves differs (Table 9 4)

5) The strength of the response varies with the intensity of the stimulation (Fig 9 54)

6) If two afferent nerves are stimulated simultaneously with weak shocks, the strength of the response may be larger than expected, exceeding the apparent arithmetical sum of the two individual responses This is *spatial summation*

7) If two afferent nerves are stimulated with strong shocks, the resulting response may be less than expected, less than the apparent arithmetical sum of the individual responses This is known as *occlusion*

8) Time required for transmission of the excitation through the spinal cord indicates that more than one synapse is traversed, that is, the flexion reflex involves interneuronal activity

In considering the implications of these results it is necessary to relate all of them to the last one, to the presence of connector or internuncial neurons and more than one synapse

Table 9 4

Strength of contraction of *M Tibialis Anticus* (flexor of the foot) in response to stimulation of various cutaneous, sensory nerves Upon direct stimulation of the motor nerve the maximal force of contraction of the muscle was 2,160 gm

Afferent Nerve Stimulated	Tension of Maximal Reflex Tetanus in Grams	Reflex Tension Expressed as Percentage of Maximal Motor Tetanus
Internal saphenous	800	32
Superficial obturator	165	6 7
Deep obturator	400	16
Nerve to quadriceps and sartorius	1190	44
Musculocutaneous branch of peroneal	1700	69
External plantar	1240	50
Internal plantar	1330	54
Small sciatic	680	28
Hamstring	565	23
Nerve of sural triceps	300 (rather low)	12
Total	8370	

Creed et al , 1932

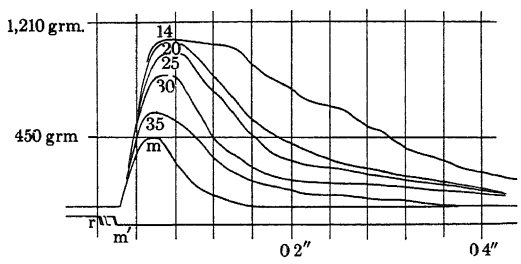

Fig 9 54 Myograms of flexor reflex of tibialis anticus muscle of spinal cat m was recorded after a single shock was applied to the motor nerve the other curves were obtained by increasing the intensity of a single shock applied to the ipsilateral popliteal (a sensory) nerve (Sherrington 1906)

Sherrington inferred that activity brought into the spinal cord via any one afferent nerve is distributed eventually to a variety of collections or "pools" of motor neurons (Fig 9 55) Furthermore, any given group or pool may receive activity from a variety of afferent nerves Finally, the influence of the afferent fibers (or better, the connector fibers) upon motor neurons is not all-or-nothing in magnitude, but is graded such that it is sometimes too weak to be effective, and sometimes reaches a maximum that cannot be surpassed no matter how much stronger the stimulus is made This graded, nonpropagated influence is the central excitatory state (CES) referred to in chapter 1

The hypothesis of the CES explains the first seven observations listed above Tetanus, for example, follows accumulation of CES as a result of the arrival of successive impulses upon motor neurons Any given motor neuron may therefore discharge more impulses and at a higher frequency, and neurons at first not active will be stimulated by accumulation of CES at their membranes Observation 6, spatial summation, is interpreted to mean that each of the weak shocks had a subthreshold effect upon neurons common to the two pools, consequently, when the two weak shocks were applied simultaneously to the two afferent nerves they stimulated neurons that had not discharged impulses following either of the weak shocks alone These particular neurons are said to belong to the *subliminal fringe* of neurons in each neuron pool Similarly, in the experiment showing occlusion, the maximal stimulation of the motor neuron pools supplied by the two afferent nerves included a significant number of neurons that were made active by either stimulus when it was applied alone The result of simultaneous stimulation, therefore, could not be as large as the apparent sum of the two individual stimulations Neurons so affected by two afferent stimulations are said to lie in the region of *central overlap* of the two pools, and the afferent impulses are said to show *convergence* upon these neurons Convergence is also required for explanation of spatial summation, as above

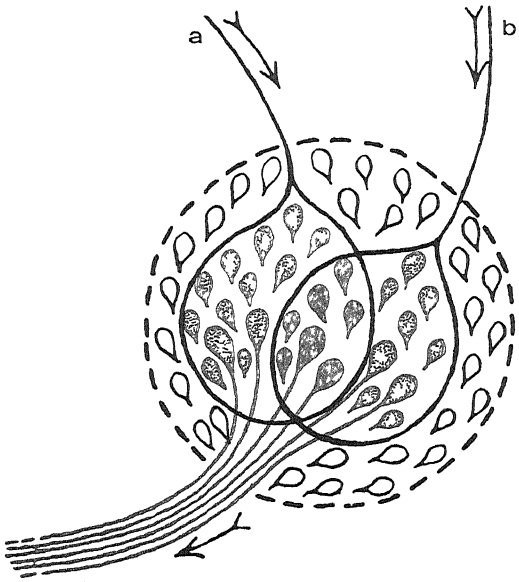

Fig 9 55 Diagram that illustrates hypothetical relationship between excitatory afferent fibers (*a b*) as they end on motor neurons in two pools (enclosed by schematic afferent axons) Motor neurons in the portion common to the two terminal collections can be excited via either afferent This pattern explains the results listed in Table 9 3 (Creed et al 1932)

STRETCH OR MYOTATIC REFLEX

The adequate stimulus which elicits this reflex is a stretch of the muscle If the stretch is performed rapidly a nearly synchronous volley of impulses enters the cord, the reflex response is abrupt and occurs with only the briefest central delay The prototype of these reflexes is the patellar reflex or knee jerk in which a sharp tap on the patellar tendon produces a contraction of the quadriceps muscle The receptors involved in this reflex are the annulospiral endings of the muscle spindle The reflex shows no *after-discharge*, that is the response ceases immediately after the stimulus terminates The measurement of central latency is difficult to achieve by myographic methods since the latency is so short and the input volley not quite synchronous The electrophysiological method to be described below gives a period of about 0 5 to 0 9 msec for the central latency of the patellar reflex

In addition to investigating the responses to a rapid stretch of muscle, it is possible to study the reflex response to a continuous stretch of extensor muscles (Fig 9 56) Since two types of response exist to stretching extensor muscles, the response to a quick stretch is termed the phasic response, whereas the response to continuing stretch is called the tonic response Two components of the tonic reflex response can be observed in the myographic record (Fig 9 56), there is an initial, rapidly rising component which is phasic, and then a sustained, slowly-falling tension which is the tonic component The true course of the reflex, however, can only be determined by excluding the passive tension developed by the muscle This is done by cutting the nerve to the muscle and repeating the experiment A curve of passively developed tension (Fig 9 56) is obtained which can be subtracted from the tension developed when the nerve was intact

The tonic component of the stretch reflex is clearly important in maintaining posture Extension of the muscle, as by swaying away from the center of gravity, activates the stretch reflex and restores the muscle to its initial length The concept that standing may be reflex in nature arose from observations on decerebrate animals in which the limbs are hyperextended Here "reflex standing" appears to be taking place The extensor muscles are reflexly activated by any slight stretch of the muscle Other factors play a role such as a release from inhibiting influences from higher centers but the reflex nature of the rigidity is demonstrable by sectioning the dorsal roots of a single limb, the rigidity then disappears

Another fundamental phenomenon can be observed in these experiments Stretching of antagonist muscles such as the semitendinosus

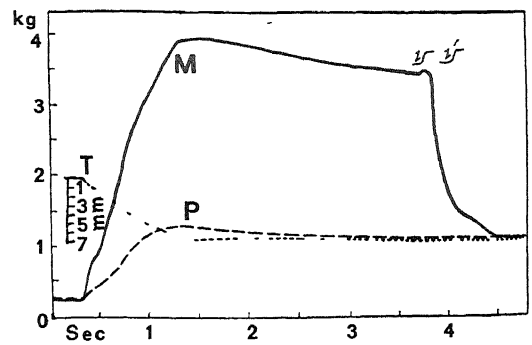

Fig 9 56 Experiment that proved that stretch reflex is truly a neural reflex When muscle was stretched by fall of table (*T*) the contraction of the muscle with normal innervation (*M*) exceeded the elastic resistance of the denervated muscle (*P*) by the difference between *tracings M* and *P* Between *i* and *i'* a stimulation of an ipsilateral nerve inhibited the reflex contractions (Creed et al 1932)

or biceps femoris causes a decrease in reflex tension in quadriceps (Fig 9 57) Indeed, stretching of the biceps causes complete disappearance of the myotatic reflex evoked by sustained stretch to the level given by passive tension alone (curve P) (Fig 9 57) This depression of reflex activity caused by stimulation of specific nerves, in this case the ipsilateral antagonists, is known as *inhibition* and will be studied in greater detail later Inhibition does not simply consist of a lack of reflex activity or a capturing of the motor pathways by the inhibiting nerve It will be shown later that the inhibiting neurons cause a change in the membrane potential of the motoneuron tending to stabilize the motoneuron against responding reflexly

As one might expect, the stretch reflex can be interrupted by section of the dorsal or ventral roots, by division of the nerve to the muscle, or by destruction of the related portion of the spinal cord The afferent fibers in the dorsal roots are large, myelinated, and rapidly conducting fibers of the A group The muscle fibers upon which the motor fibers end are predominantly of the red variety, these particular fibers are responsible for maintenance of posture, and are more plentifully supplied with large diameter motor fibers than are the pale fibers of flexor muscles The name, myotatic unit, is given to the stretch receptor, afferent fiber, reflex connection in the spinal cord, motor neuron, and striated muscle fiber

The principle of *reciprocal innervation* is one of the broad generalizations about spinal reflex activity that resulted from Sherrington's early work on excitation and inhibition The principle states that the flexors and extensor reflexes of the same limb cannot be simultaneously active, if a flexor reflex is evoked, the extensor is inhibited and vice versa For instance, the afferent nerves evoking an extensor reflex have connections going to the flexor motoneurons of the same limb causing them to be inhibited (Fig 9 58) When a flexor reflex is elicited, its connections on the extensor motoneurons cause the extensor reflexes to be inhibited The extent of inhibition in all such cases is proportional to the reflex activity taking place so that a primitive form of organization is taking place at the segmental level and on the limb of one side But at the same time the evocation of a reflex on one side causes opposite effects on the motoneuron pools of the opposite limb Thus, when a flexor reflex is obtained on one side of the animal, the flexors of the opposite limb are inhibited and the extensors are facilitated Two examples of such integrated contralateral activity are the crossed extensor reflex and Phillipson's reflex The *crossed extensor reflex* accompanies a flexion reflex and is obtained by pinching the limb of a spinal or decerebrate animal (Fig 9 59) The pinched limb withdraws but the contralateral limb extends Similarly *Phillipson's reflex* is obtained from the extended limb of a spinal or decerebrate animal, flexing the limb forcibly produces the *clasp-knife reflex* and causes the opposite limb to extend (see Sherrington, 1906) Reciprocal innervation is very useful in more elaborate activities such as walking where it is obviously necessary to have complete synchronization of flexor and extensor activity The presence of reciprocal innervation ensures that accidental evocation of simultaneous reflex antagonist

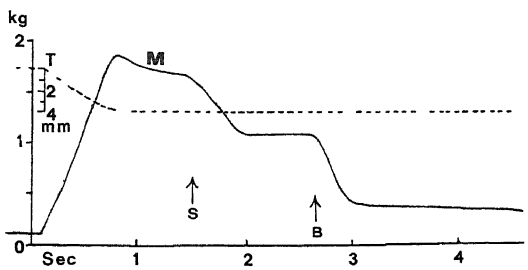

Fig 9 57 Reflex response of quadriceps to stretch (signalled by fall of table *T*) At *arrow S* a stretch was applied to semitendinosus followed at *arrow B* by stretch applied also to biceps The graph shows that stretch applied to the opposing muscles the flexors of the knee inhibited the reflex response in the extensor quadriceps (Creed et al 1932)

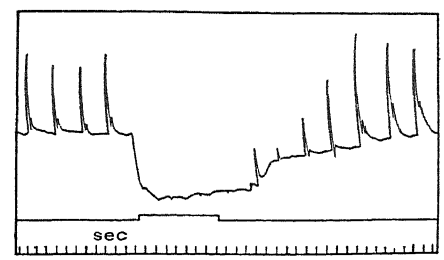

Fig 9 58 Inhibition of knee jerk during central stimulation of a portion of the sciatic nerve Upper tracing is record from myograph middle tracing signals period of central stimulation bottom tracing is time in seconds (Sherrington 1906)

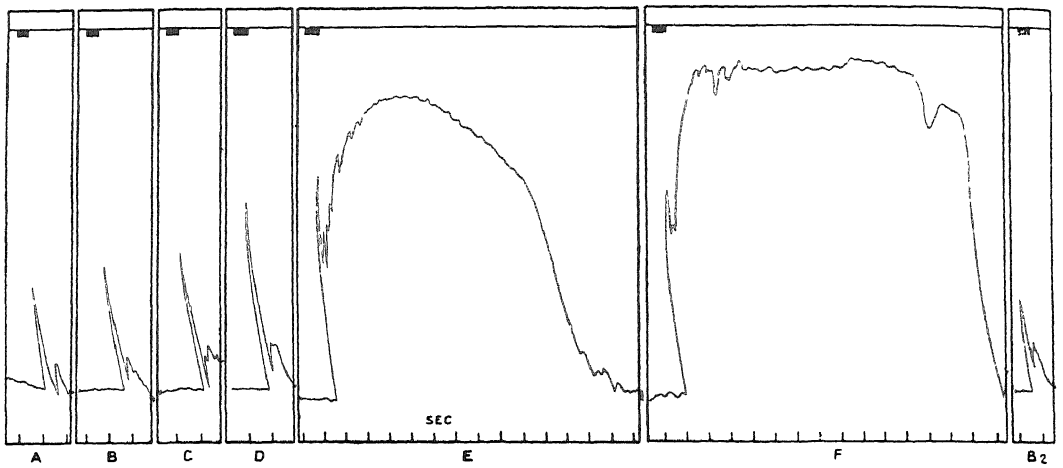

Fig 9 59 Crossed extensor reflex strength and duration of contraction as strength of stimulus applied to contralateral cutaneous nerve was increased (*tracings A–F* B_2 is a repeat of stimulus in *tracing B*) In each instance the stimulus was applied in the form of 12 shocks in ½ sec (Sherrington 1906)

activity does not occur, when one reflex is active, the other is inhibited

Electrophysiology of Spinal Reflexes

Sherrington knew that the latent period of the flexion reflex depends upon the strength of the stimulation, and has a minimal value of about 11 msec (Fig 9 60) To measure accurately the much shorter latencies of the stretch reflex required the development of more sensitive apparatus, including electronic stimulation and recording Electrical potentials recorded when nerve impulses are carried by the ventral roots are referred to as reflex responses, as were myographic recordings of tension If a nerve containing sensory fibers from a muscle is stimulated centrally so that impulses are sent into the spinal cord, a recording of activity in the ventral root will show two waves having different characteristics and latencies (Fig 9 61) An early, large spike lasts about 1 msec , followed by a series of irregular discharges lasting for about 10 msec The first discharge can be evoked also by a quick stretch of an extensor muscle, so that it is the electrical counterpart of the stretch reflex The later, irregular discharge can be evoked alone by stimulation of a sensory nerve from skin, it is the electrical counterpart of a flexor reflex

FIBER TYPES

Afferent nerves are divided into four categories in accordance with their fiber diameter and velocity of conduction, as follows Group I,

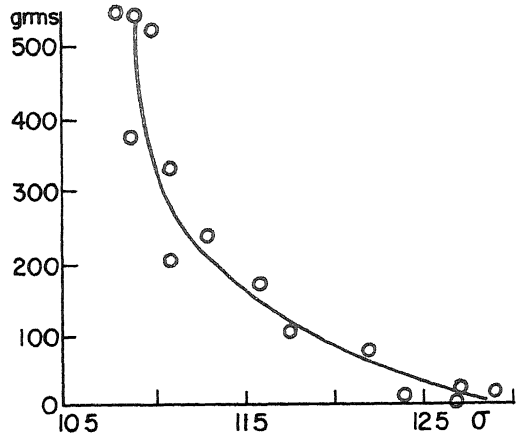

Fig 9 60 Relationship between force of reflex contraction and latency of the response As strength of a stimulus was increased force increased and latency became shorter (Creed et al 1932)

12 to 21 μm , Group II, 6 to 12 μm , Group III, 1 to 6 μm , Group IV consisting of C fibers less than 1 μm in diameter Groups I, II, and III_a correspond to fibers in the A category, group III corresponds to AΔ All somatic nerve trunks contain the afferent groups II, III, and IV Group I, containing the fastest afferent fibers is present only in nerves from muscles and is associated with afferents from the muscle spindle (group I_a) and the Golgi tendon organ (group I_b)

Motor nerves consist of two groups of fibers One group, the α motoneuron innervates the striated muscle fiber, is 9 to 13 μm in diameter and constitutes about 70% of all the effer-

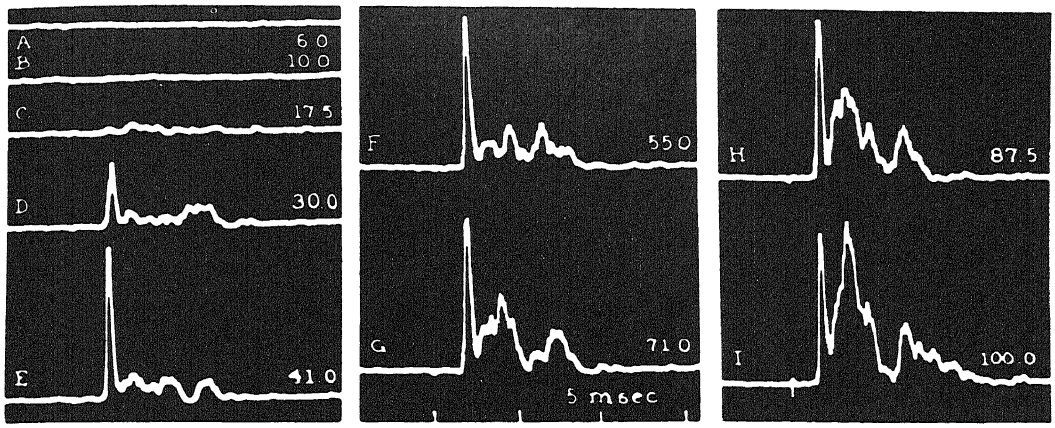

Fig 9 61 Dorsal root-ventral root reflex discharges from first sacral segment Records *D–F* show clearly the appearance and increase in the early spike of short latency as strength of the afferent stimulation was increased (figures on right of each record) The second later and more irregular waves are also shown (Lloyd 1943a)

ent fibers, the second group are the γ efferents, 3 to 6 μm in diameter and are the efferent fibers to the intrafusal muscles of the spindle

THE MONOSYNAPTIC REFLEX

A rapid reflex response of short latency is elicited by exciting type I sensory fibers This latency includes time for conduction through the fibers, plus time for excitation across any synapse As measured by stimulating a dorsal root and recording from the ventral root the shortest delay not accounted for by conduction in fibers is around 0 5 msec This appears to be the delay of a single synapse More precise measurement of the synaptic delay may be performed by stimulating neurons directly within the spinal cord in the region of the motoneurons (Fig 9 62) At low stimulus intensities, interneurons within the cord are fired, at higher stimulus strengths the motoneuron itself is excited The difference in time between the interneuronal and the motoneuron response is a measure of the synaptic delay By this direct method, the delay is found also to be 0 5 msec It therefore may be concluded that the early spike of the reflex discharge arises from a reflex arc in which only one synapse is present between the afferent and efferent neurons; no internuncial neurons are interposed between these. For this reason this reflex as recorded in this fashion is referred to as *monosynaptic reflex*

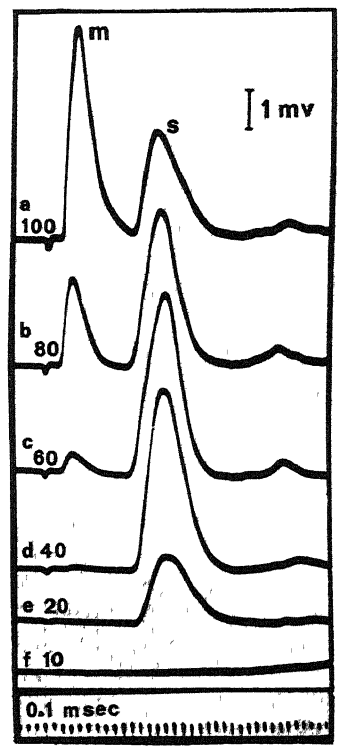

Fig 9 62 Measurement of central synaptic delay Records are from ventral root of cat after decerebration plus section of spinal cord Stimulus (slight downward blip in records) was applied by needle electrodes in intermediate grey matter of spinal cord Strength of stimulus was strongest for record *a* weakest for record *f* First spike represents direct stimulation of motor neurons second spike is result of activation via a single synapse Inverval between onset of the two spikes measures synaptic delay (Renshaw, 1940)

MULTISYNAPTIC REFLEXES

The electrical discharge which corresponds to the flexor reflex has a longer latency—of the

order of 3 to 5 msec It therefore must contain more than one synapse, and internuncial or connector neurons interposed between the input and output The afferent nerves involved in evoking the reflex are members of groups II, III, and IV Assuming that each synaptic delay is about 0 5 msec and that the transit time over the short interneuronal axons is negligible the number of neurons probably involved in the reflex is between 6 and 10 (reflex latency per synaptic delay) In this reflex action potentials continue to appear in the ventral root as an after-discharge, which results from persistent activity over delay pathways between the input and the final motoneuron At least two basic circuits exist which may give rise to an after-discharge (Fig 9 61) One arrangement of neurons consists of a series of delay pathways in parallel without any feedback from a subsequent to a preceding neuron This is called a *multiple chain network* A second neural configuration consists of a chain of neurons so arranged that some of the neurons further down in the chain may feedback to earlier neurons and re-excite them Such chains are called *reverberatory networks* for they give rise to activity which reverberates back to the first cells in the chain At present, the relative contribution of each network to after-discharge in multisynaptic reflexes is unknown

FACILITATION AND TEMPORAL SUMMATION

Spatial summation was attributed to the circumstance that two input pathways may contain nerve fibers which terminate on the same neurons The first or conditioning stimulus can be applied to the nerve from one head of the gastrocnemius muscle, the second or test stimulus which is strong enough to evoke a reflex is applied to the nerve from the other head of the muscle If the two stimuli are applied simultaneously, an augmentation of the response by as much as 300% may be observed If, however, the conditioning volley is separated from the test volley, it gradually loses its effectiveness so that when they are 10 msec apart the effect has almost disappeared It is clear from these experiments that a conditioning volley which causes no reflex response may give rise to facilitatory effects which may last for as long as 10 msec or more This kind of *residual facilitation* can occur in pathways where no internuncials seem to be present as in extensor nuclei of the cord, or the same results can be obtained in the flexor nuclei How a facilitation independent of internuncial delay networks can occur will be explained later in terms of the effects of the afferent volley upon the membrane potential of the motoneuron These experiments raise the question of whether temporal summation is possible in the nervous system, that is, whether two successive stimulations of a single afferent pathway can evoke a response greater than the predicted sum of the two individual responses The question is, does the residual facilitation (CES) last longer than the refractory period of the afferent pathway? The answer seems to be that temporal summation cannot occur naturally, but can be demonstrated when an electrical stimulus is applied directly to the motor neuron (Lorente de Nó, 1938a and b) In this case there is no afferent pathway with a measurable latency

ELECTRICAL RESPONSE OF THE MOTOR NEURON

The Excitatory Postsynaptic Potential (EPSP). As noted above, Eccles (1953) and co-workers inserted finely drawn-out microelectrodes made of glass and filled with KCl or NaCl solution into the cell body of motoneurons of the spinal cord for study of local potential changes They found that when the microelectrode is inserted, a resting potential of about −70 mv is observed, with the interior of the cell negative to the outside If the motoneuron is antidromically excited, i e , by stimulating its axon, the motoneuron is excited without the intervention of the synapse An action potential with an overshoot of about 20 mv appears Thus, antidromic excitation gives rise to an action potential in the postsynaptic cell, the motoneuron, which is no different in its general characteristics from that obtained from squid axon or the muscle fiber

The events of interest in synaptic excitation, however, occur when excitation is delivered orthodromically, i e , to the afferent neuron of the dorsal root, so that the presynaptic endings of this neuron are excited In such experiments in which a synapse is present, in recordings from the postsynaptic cell an additional potential appears which is a sign of synaptic depolarization Figure 9 63 shows the response of the motoneuron to a presynaptic volley The slow potential which appears just before the

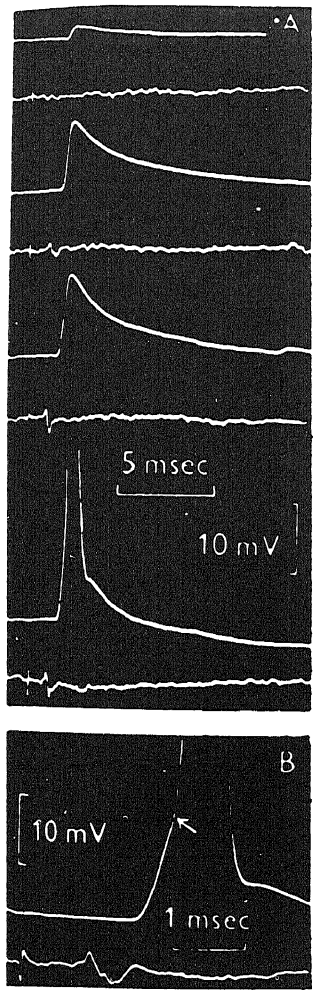

Fig 9 63 Intracellular recording of membrane potential changes in a flexor motor neuron as a result of stimuli of various intensities applied to a sensory nerve The upper record of each pair is the membrane potential the lower stimulus timing and strength Note increase in sweep speed in *B* to show the synaptic potential that anticipates the spike The first three potential traces show only the synaptic potential with no spike (Brock et al 1952)

action potential is called the excitatory postsynaptic potential or EPSP, and is the local, electrical sign of the CES of Sherrington It consists of a depolarization of the membrane which may last for 20 msec and can best be seen when the extent of depolarization is insufficient to give rise to an action potential When the membrane potential is decreased to a critical value of about −60 mv, a nerve impulse is generated and an action potential appears on the EPSP Temporal summation of such EPSP is also possible, if two subliminal volleys are sent in over the same nerve, each volley produces an effect which is manifested by an EPSP The EPSP's will then sum and if the critical level of depolarization is reached, an impulse will be set off

The EPSP is monophasic and nonpropagated, it represents a depolarization which is localized to the soma of the motoneuron It is not all-or-none in character since it can be augmented simply by increasing the intensity of the input volley Moreover, the EPSP's of different inputs can sum on a postsynaptic cell to produce a greater depolarization These characteristics show that the EPSP is produced in a process which is fundamentally different from that of the action potential, and illustrate the fact that EPSP has the properties Sherrington attributed to CES Several lines of evidence indicate that the EPSP arises from a depolarization of the postsynaptic membrane and an increase in permeability to both sodium and potassium ions

Inhibitory Potentials. If a monosynaptic reflex is evoked by stimulation of afferent fibers (orthodromic excitation), an inhibition of the reflex can be produced by stimulating an ipsilateral antagonist nerve as described more fully in the section on inhibition The effect of the inhibitory stimulus is to cause a hyperpolarization of the postsynaptic membrane in a direction opposite to that of the EPSP (Fig 9 64) This hyperpolarization consequent upon an inhibitory stimulus is called the inhibitory postsynaptic potential or IPSP It begins to develop a bit later than a monosynaptic EPSP, but its time course is otherwise the same as that of EPSP, of the order of 20 msec, and corresponds to the curve of inhibition obtained from reflex studies Indeed the IPSP is a mirror image of the EPSP in the same motoneuron The IPSP causes a hyperpolarization of the membrane and renders it less excitable according to the principles of peripheral neurophysiology Any EPSP which occurs during an IPSP will generate currents which will be less effective in causing excitation of the cell

The problem of determining the nature of the currents responsible for the IPSP has been attacked by using doubled-barrelled microelectrodes for simultaneously passing a current and recording the membrane potential Setting the membrane potential at −80 mv will cause the disappearance of the IPSP The potential −80 mv is the average of that determined by

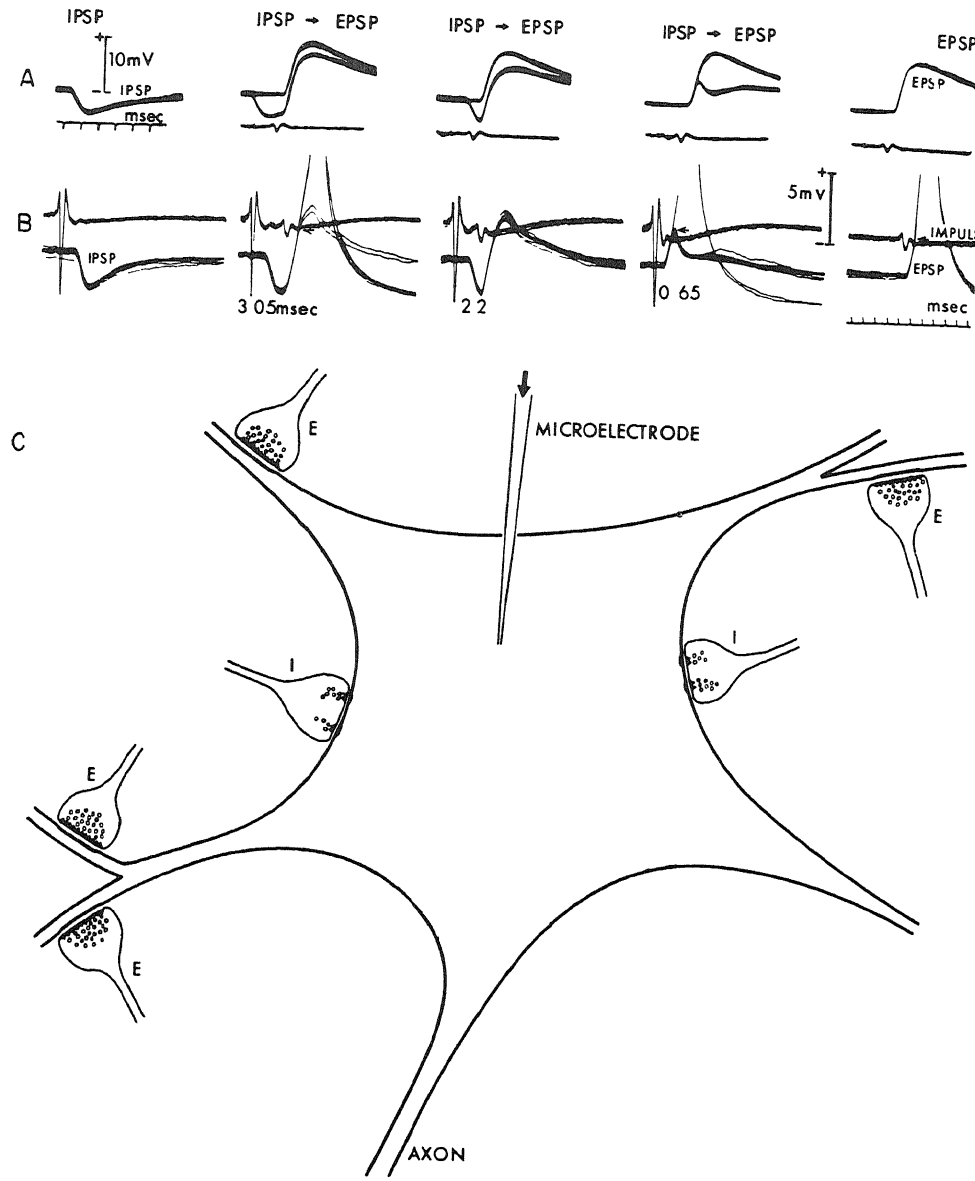

Fig 9 64 Diagram of neuron (*C*) with excitatory (*E*) and inhibitory (*I*) synapses and with two series of records of membrane potential recorded with microelectrodes (*A* and *B*) On these records the deflections that signal excitation or inhibition are labeled *EPSP* and *IPSP* respectively (Eccles 1967)

potassium (−70) and chloride (−90) suggesting that the IPSP results from an increased flow of K^+ out and Cl^- in, so that the inside becomes more negative Further evidence points to chloride as the principal ion involved in producing the EPSP The method of electrophoretic injection has been used to demonstrate this One barrel of a double microelectrode is filled with KCl and made negative so that this electrode effectively drives chloride ions into the cell, it is a hyperpolarizing current since it is internally negative The other barrel of the electrode records the IPSP Under these conditions the injection of chloride into the cell converts the IPSP elicited by a group I_a afferent volley from a hyperpolarization to a depolarization (EPSP) The injection of chloride had caused an increased internal concentration of chloride The arrival of the inhibitory stimulus then results in an increased permeability to chloride, but

because the chloride ionic gradient is now opposite to its normal direction, chloride now flows out and makes the inside of the cell less negative This causes depolarization instead of hyperpolarization A number of anions were injected internally and all those which were less than a certain hydrated ion diameter caused a reversal of the IPSP to an EPSP Apparently the inhibitory substance opens pores which allow ions below a certain size to pass Since chloride is the only anion which exists in a high enough concentration to flow in during such an inhibition, it is presumed that chloride is the main contributor to the inhibitory currents which flow

TYPES OF INHIBITION

Three kinds of inhibition have been extensively studied *a) postsynaptic, b) presynaptic,* and *c) Renshaw cell* or *recurrent* inhibition A fourth type, called indirect inhibition and extensively discussed by Sherrington, is now considered to be not a type of inhibition per se, but rather a form of occlusion

Sherrington and his associates (Fig 9 65) investigated the time course of the inhibitory process Using a flexion reflex as the indicator and a contralateral stimulus for inhibition, they found the central inhibitory process or CIS to be maximal when the inhibitory volley preceded the excitatory stimulation by about 80 msec

Postsynaptic or Direct Inhibition. Each of the three types of inhibition has been studied

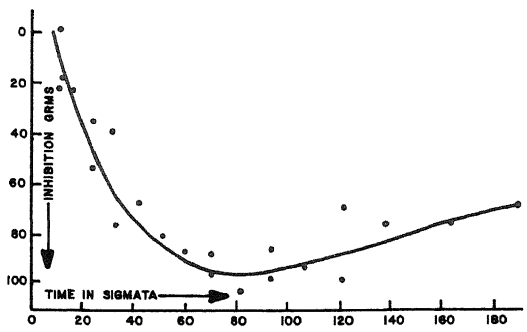

Fig 9 65 Latent interval for development of central inhibition Inhibition was created by stimulation of a contralateral cutaneous nerve at various intervals before ipsilateral stimulation evoked a flexion reflex Inhibition was maximal if inhibitory stimulus preceded excitatory stimulus by 80 msec Ordinate is percentage of inhibition, plotted inversely abscissa is duration of interval between the two types of stimuli (Creed et al 1932)

in similar experiments, and their time courses have been determined by utilizing two separate afferent stimuli that have opposing actions upon a given motor neuron pool For example, stimulation of I_a fibers in a dorsal root will initiate a monosynaptic reflex and EPSP on the motor neurons, whereas stimulation of type II fibers in an ipsilateral cutaneous nerve may inhibit the monosynaptic reflex by creating an IPSP on those same neurons The presence of the inhibitory process is detected by applying both stimuli in a single experiment, with variation of the interval between them Thus, if the inhibitory stimulus is given first by about 0 5 msec , there will be maximal inhibition of the subsequent monosynaptic response If the inhibitory stimulus follows the test stimulus by 1 msec , the inhibition arrives too late to block the reflex Utilizing this technique where the inhibitory stimulus is a "conditioning" stimulus (but not as Pavlov used the term), the time course of development and persistence of the inhibitory process can be revealed (Figs 9 66 and 9 67) It is this evidence that justifies the statement above that inhibition and IPSP have the same duration The observation that the inhibitory stimulus must precede the test stimulus by a minimal interval of 0 5 msec is taken to mean that the inhibitory pathway involves at least one more synapse than the excitatory reflex This interneuron in the inhibitory pathway possesses the ability to secrete a substance at its terminals which hyperpolarizes the membrane and leads to an IPSP Thus, a neuron which is normally excitatory to other neurons may exert an inhibitory action by the interposition of an inhibitory neuron Other mechanisms which have been proposed include terminating the neuron on a special region of the postsynaptic neuron so that it can have inhibitory effects on special regions of the postsynaptic cell

Postsynaptic inhibition is by definition the inhibition that has the characteristics that correlate with genesis and persistence of the IPSP as recorded using a microelectrode inserted into a motor neuron It is very susceptible to strychnine injection which can completely abolish it This effect of strychnine is the basis for the explanation of its convulsant activity— All postsynaptic inhibition having been removed, the slightest stimulus causes a tremendous extensor response

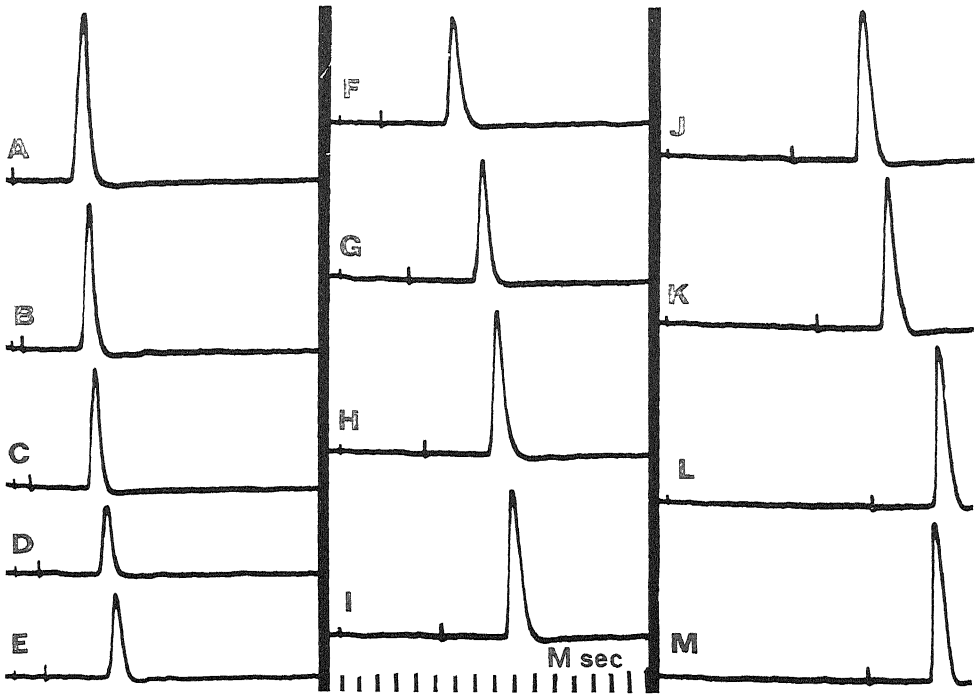

Fig 9 66 Inhibition of two neuron reflex to gastrocnemius induced by weak afferent volleys in deep peroneal nerve The height of the spike signals the strength of the reflex the interval between the two blips at the *left* of each record shows that there was variation in the time between the two stimulations As this interval was lengthened the strength of the response was at first inhibited then recovered its initial voltage (Lloyd 1946)

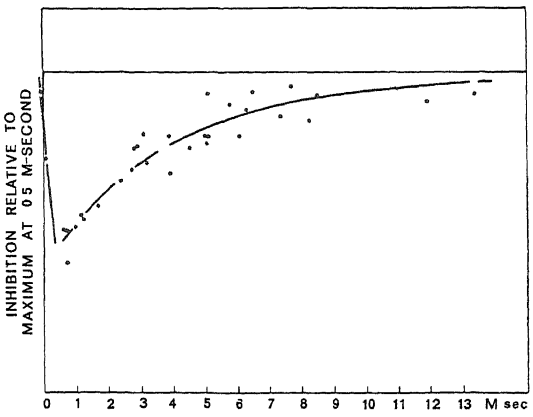

Fig 9 67 Strength of inhibited response relative to control plotted against interval between two stimuli The shortness of the latency for maximal inhibition cannot be fully accounted for Data from Lloyd 1946

Presynaptic Inhibition Early in the studies of the electrical responses evoked by reflex action, electrodes were placed on the surface of the spinal cord or on dorsal roots and large potentials which were positive to distant regions, called P waves were recorded It was suspected that this positivity might be the sign of some inhibitory presynaptic activity going on in the afferent terminals in the spinal cord To demonstrate presynaptic inhibition, a reflex response is elicited in extensor motoneurons This reflex will be inhibited if it is preceded by stimuli from any nerve entering the cord Group I_a and I_b fibers are most effective in causing the inhibition but groups II and III will also serve The time course of such an inhibition is shown in Figure 9 68 Unlike postsynaptic inhibition, maximum presynaptic inhibition is observed when the inhibitory stimulus precedes the excitatory by about 20 msec The inhibition may endure for as long as 200 to 300 msec and is extremely resistant to strychnine

Several lines of evidence indicate that this inhibition is presynaptic Recording within the motoneuron at the time that inhibition is produced shows no changes in the membrane potential, neither a hyperpolarization or a depolarization is produced by an inhibitory volley Instead, the magnitude of the EPSP which is set up by the reflex volley is diminished by the inhibitory stimulus and the change in magnitude of the EPSP parallels the curve of inhibi-

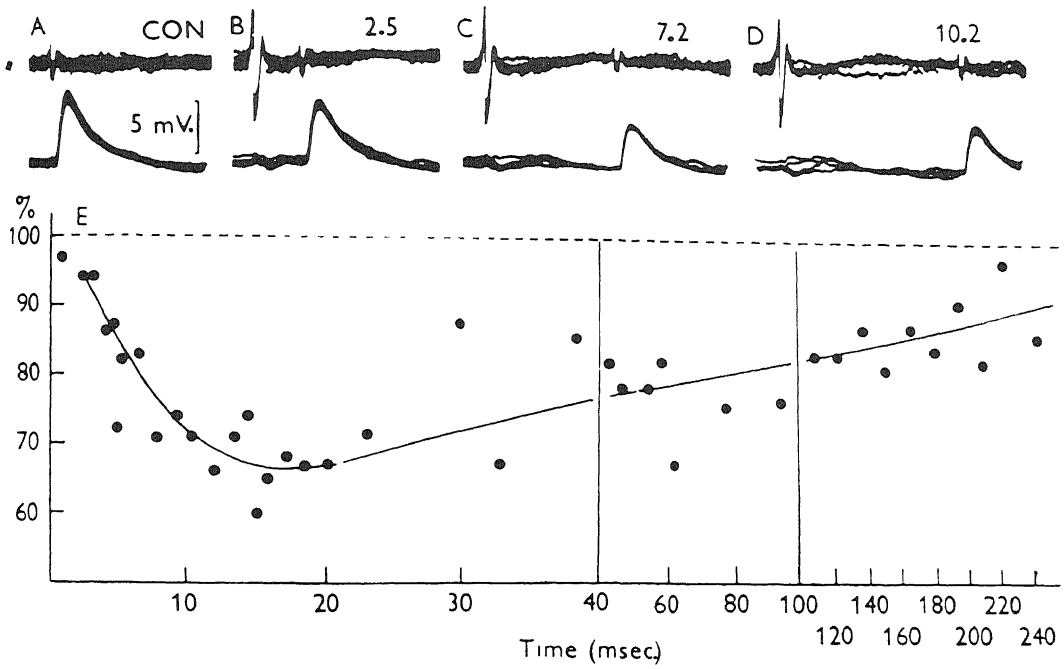

Fig 9 68 Presynaptic inhibition as a function of interval between inhibitory and the stimulating volleys *A–D* show time relations of volleys presynaptic inhibition is disclosed as variability in height of EPSP in lower of each pair of records

tion (Fig 9 68) The usual explanation for these observations is that the inhibition is due to some interaction at the terminals of the two groups of afferent fibers Activity in the inhibitory terminals apparently prevents activity in the excitatory endings A presynaptic depolarization may affect the amount of transmitter released from the presynaptic terminals Since long delays are involved in presynaptic inhibition, many interneurons are interposed between the first and last neurons of the chain

Renshaw Cell Inhibition. In 1941 Renshaw discovered that an electrical stimulus applied to motor axons and carried by them back into the ventral grey column causes an inhibition of all types of motoneurons at the segmental level This type of inhibition has therefore been called antidromic because the inhibition is evoked by "backwards" conduction via the motor roots into the spinal cord When such antidromic excitation is used, an after-discharge of quite high frequency is present in the recording from the ventral root Microelectrode recording has shown that the discharge does not originate in the motoneuron but in neighboring cells near the motoneuron—in cells which discharge with a high frequency when the antidromic excitation occurs At the same time the motoneuron is inhibited These neighboring cells are therefore believed to cause the inhibition The motoneuron displays a hyperpolarization which has all the characteristics of an inhibitory postsynaptic potential and the IPSP lasts for the period of time (Fig 9 69) corresponding to the discharge in the neighboring interneurons (known as Renshaw cells) An anatomical pathway has been suggested to explain these results (Fig 9 70) The motoneuron gives off a collateral to the Renshaw cells, the Renshaw cell axon returns to the motoneuron and inhibits it

The repetitive discharge of the Renshaw cell is presumed to be caused by an accumulation of acetylcholine at the junction between the motoneuron collateral fiber and the Renshaw cell It has been shown, for example, that the discharge of the Renshaw cell may be prolonged by anticholinesterases which allow acetylcholine to accumulate It is also possible to inhibit the discharge with β-dihydroerythroidine, a substance which blocks the action of acetylcholine The functional significance of this pathway is not clear It appears to serve as a general synaptic inhibitor and may act to limit the frequencies of impulses going to the motor end-plate

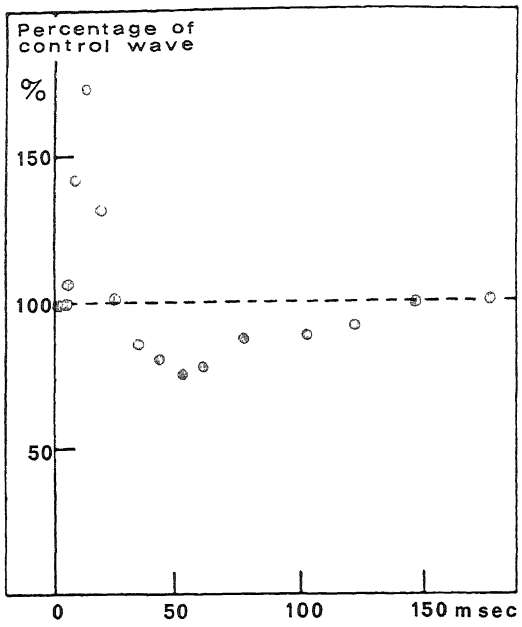

Fig 9 69 Time course for development of inhibition of the Renshaw type when antidromic stimulation of a motor neuron's axon precedes excitation via a dorsal root or sensory nerve (Renshaw 1940)

ELECTRICAL AND CHEMICAL TRANSMISSION

As noted earlier, events at a synapse may be interpreted according to either a chemical or electrical theory of synaptic transmission The chemical theory of transmission attributes the response of the postsynaptic cell to a chemical substance (transmitter) released from the presynaptic nerve terminals (Table 9 5) The electrical mechanism of transmission presupposes the activation of postsynaptic neurons by electrical currents flowing out from the presynaptic terminals into the postsynaptic cell Examples of each of these types of transmission may be found in various kinds of synapses among vertebrates and invertebrates It may be stated, however, that no evidence of electrical transmission at mammalian synapses has as yet been obtained

The chemical mechanism of transmitter release and action has been presented in section 1, chapter 3, and is summarized in Figure 9 48 γ-Aminobutyric acid is the compound most often considered as a possible inhibitory transmitter (Mitchell and Srinivasan, 1969, Curtis et al , 1970)

The Muscle Spindle and Stretch Reflexes

From the ultimate control process in skeletal muscle, (the release of calcium ions from the inner surface of the sarcolemma membrane), the origin of this control has been traced back along the course of the axons that originate in the spinal cord (Fig 9 71) In the cord the interaction of neurons has been considered, and the influence of two classes of afferent fibers has been described These are the I_a fibers from muscle that activate monosynaptic reflexes, and the types II, III, and IV fibers that provoke the flexion reflex Because the I_a fibers originate in muscle and are capable of evoking a stretch reflex, they function as the afferent component of the segmental control system for muscle It is necessary, therefore, to consider where they come from and what are the properties of the receptor or detector element they innervate (see Barker, 1962) It turns out that the detector element, itself, has a motor innervation different from that of the more typical muscle cells, and that this second or gamma (γ) innervation is a significant determinant of the sensitivity of the detector elements How the reflexes so established are integrated into attitudes of posture and into locomotion will be described in the succeeding chapter

When the position of the body is displaced backwards as in swaying, the extensor muscles of the leg such as the quadriceps are stretched As a consequence, the stretch reflex is called into play and the extensor muscles shorten to fix the joint The receptors involved in such a postural adjustment are the annulospiral endings of the muscle spindle, endings which are also responsible for the phasic and tonic components of the myotatic reflex

TYPES OF ENDINGS AND FIBERS

A *muscle spindle* (Fig 9 72) contains both sensory and motor elements The motor parts are composed of two types of muscle fibers, intrafusal in location, having their nuclei centrally collected in the case of the nuclear "bag" fibers, or longitudinally distributed in the nuclear "chain" fibers Both are innervated by γ motor fibers, designated as γ_1 and γ_2, respectively, and believed to serve different functions (Matthews, 1964) The primary sensory role of the spindle is subserved by nerve endings within the nuclear bag These nerve fibers are afferent type I_s; they are larger than 12 μm in diameter and have conduction velocities of more than 90 m /sec Another, secondary group of afferents originates outside the nuclear bag in the myotube region, these endings are flower spray in type and their nerves are in group II (Fig 9 73) Their function is not clear, inasmuch as stimulation of this group of fibers apparently does not evoke a stretch reflex in extensor muscles Matthews has suggested that the primary endings are responsible for dynamic as well as static signals, that is, for detection of stretch and rate of stretch, as well as for length of the muscle The secondary endings are believed to be sensitive in a static sense to length

Muscle spindles are attached at each end either to a tendon, to other spindles, or to extrafusal muscle fibers They are said to lie "in parallel" with extrafusal fibers because shortening of the latter relieves tension on the spindles Conversely, the stretching of a muscle lengthens the extrafusal fibers and exerts tension on the spindles This may be an oversimplification, in that when the end of a spindle attaches to an extrafusal fiber the spindle acquires a "series" relationship to that fiber, at least These relationships are further compli-

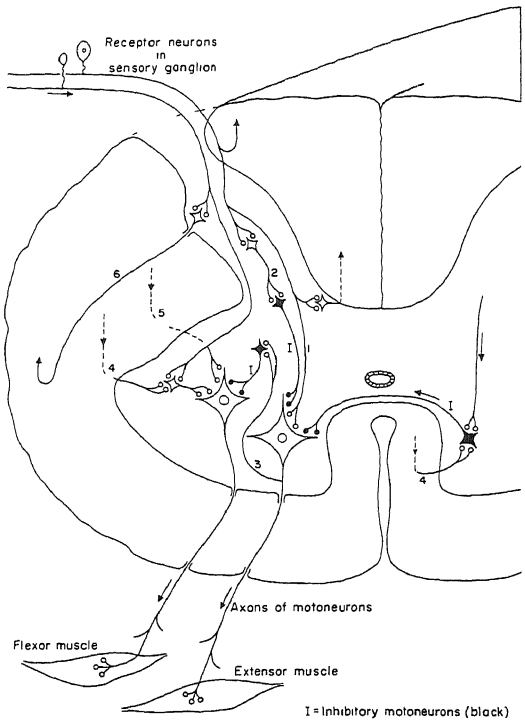

Fig 9 71 Diagram illustrating the interconnections that occur at a typical level of the spinal cord The flexor motor neuron (*left*) and extensor motor neuron (*right*) are intended to represent cells of two neuron pools Inhibitory neurons are in black and are labeled *1 1*) Connections of two-neuron arc extensor *2*) Multisynaptic pathway with inhibitory connector neuron *3*) Pathway of Renshaw type of inhibition *4*) Crossed and uncrossed input from other levels *5*) Corticospinal pathway in primates it comes directly from motor cortex *6*) Second order neuron of sensory pathway ascending to higher levels Bodian cited from Quarton et al 1967

cated by the activity of the intrafusal muscle fibers, to be described shortly

The *Golgi tendon organ* arises from the tendon of the muscle and is anatomically in series with the muscle When the muscle is stretched, the Golgi tendon organ is stretched and stimulated and when the muscle contracts, the Golgi tendon organ is likewise stretched and stimulated The Golgi organ gives rise to afferent fibers which are classified as I_b with a modal velocity of about 80 m /sec , somewhat slower than the I_a group The extent of stretch necessary to evoke a response from the Golgi tendon organ is greater than for the annulospiral ending

Gamma Efferent System The function of muscle spindles has become more difficult to describe with discovery of progressively more details of organization of the intrafusal mecha-

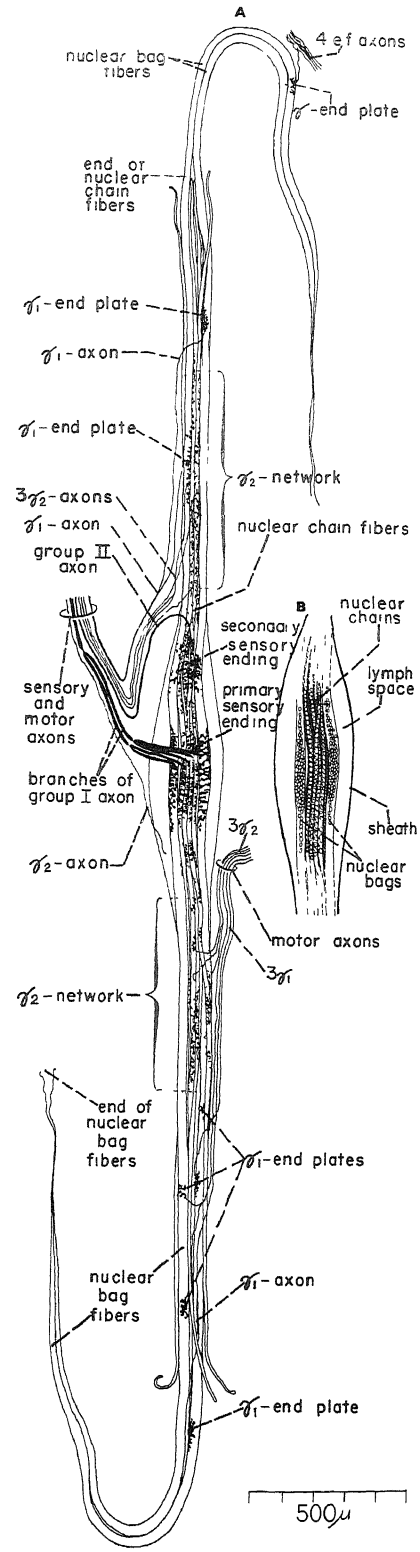

Fig 9 72 Drawing of structure and innervation of a muscle spindle (Boyd 1962)

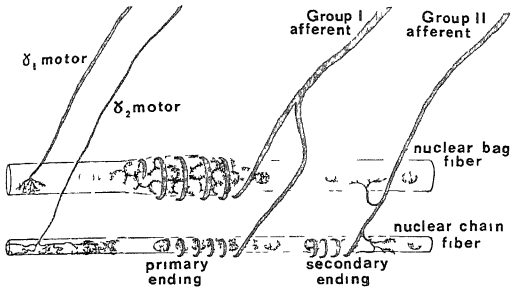

Fig 9 73 Diagram showing two types of ending primary and secondary on each of two types of fibers nuclear bag and nuclear chain Motor innervation is also shown (Matthews 1964)

nisms Not only is there the possibility that the primary ending is in parallel with most extrafusal fibers and in series with others, but as Fig 9 72 shows it is in parallel with the intrafusal fibers innervated by the γ_2 neuron, and in series with the element innervated by γ_1 These same relationships apply also to the secondary ending Consequently, it hardly seems adequate to describe the spindle as a detector that yields a negative feedback to the motor mechanisms of the spinal cord and merely inhibits any change in length of the muscle They do, of course, produce a negative feedback, but it has no simple relationship to the length of the muscle Perhaps the clearest way to explain the function of the intrafusal fibers of the mechanism is to assume that their contraction serves to control the sensitivity of the detector elements In doing this the intrafusal fibers partially isolate the sensory components from changes in the main or extrafusal fibers of the muscle Thus, contraction of a nuclear bag fiber may elongate the primary ending even though the muscle as a whole has shortened (Fig 9 74) With naturally occurring movement of the whole muscle this control of intrinsic tension permits the spindles to preserve sensitivity no matter whether the extrafusal fibers are short or long In this way the spindle may be able to signal change in the muscle under any condition of length or tension Nevertheless, the fact that relationships are in series as well as in parallel, and that intrinsic contractile elements have both types of relationship, further multiplies the possibilities of diversified function

The anatomical difference between the primary annulospiral and Golgi tendon organ is paralleled by a similar difference in their reflex responses to stretch When the annulospiral endings are in parallel with the extrafusal fibers, if a muscle containing such an ending is stretched, the annulospinal endings respond with an afferent volley in the I_a fibers, and a reflex myotatic discharge occurs in the extensor muscle These endings respond only to stretch and cease firing when the muscle shortens or relaxes On the other hand, the Golgi tendon organ responds to either contraction or extension of muscle However, it is necessary to stretch muscles considerably before any effective discharge occurs The reflex response in which the Golgi tendon organ is involved is called the *inverse myotatic reflex* or *clasp-knife reflex* If the extended limb of a decerebrate animal is flexed forcibly, considerable resistance is met until at a certain extension the limb suddenly gives way to the force The stretch of the extensor muscles beyond their normal position as a result of the forcible flexion activates the Golgi tendon organs and inhibits the extensor reflexes This type of inhibition is called *autogenic* since it arises from the very muscle from which the reflex itself was obtained

The properties of the muscle spindle that are significant for the maintenance of a fixed length of muscle are the following *a*) A passive stretch of the muscle and its spindles causes the primary endings to discharge and send impulses to the cord over group I_a fibers The discharge rate is high at the beginning of the stretch but falls off to reach a steady maintained, tonic rate of discharge from both primary and secondary endings The frequency of discharge of the spindle in the steady state is proportional to the extent to which the muscle has been stretched *b*) Adaptation of the spindle discharge is slight The tonic discharge

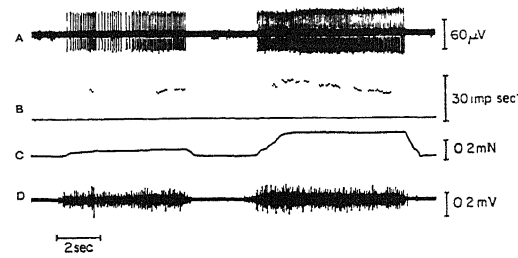

Fig 9 74 Discharge of sensory unit in muscle spindle (records *A* and *B*) as a result of tension in the intrinsic motor fibers accompanying voluntary contraction of the muscle Record *C* is force of muscle contraction *D* is electromyogram Data of A B Vallbo cited by Granit 1970 p 169

continues indefinitely as long as the muscle is kept stretched *c*) Contraction of the muscle (shortening of the muscle fibers) causes cessation of firing Shortening releases the spindle from the tension caused by extension, and the spindle is no longer mechanically excited This experimental finding demonstrates that the spindles are functionally in parallel with the extrafusal muscle fibers *d*) Contraction of the intrafusal fibers of the motor spindle results in an acceleration of the discharge from the spindle By stimulating the intrafusal fiber, the annulospiral endings are placed under stress and the endings are stimulated Contraction of the intrafusal fibers is equivalent to taking up the slack on the intrafusal fibers and placing the annulospiral endings under some degree of tension It is therefore the same effectively as passively stretching the muscle All these properties are important when the spindle acts as part of the reflex arc controlling the length and tension of a skeletal muscle

The γ efferent system presumably is involved also in the more rapid shortening of muscle such as occurs during voluntary movement Such movement can occur theoretically in either of two ways—a direct activation of the motoneuron via the corticospinal pathway, or excitation of the motoneuron indirectly through the γ efferent system (Granit, 1970) The γ efferents might be activated by descending fibers from the reticular formation Such stimulation would cause shortening of the intrafusal fibers, stretching of the annulospiral endings, and an immediate spindle discharge This discharge would then elicit a phasic reflex response of the extensor motoneuron Thus, a rapid voluntary movement might be evoked by intrafusal excitation This latter mechanism has been a subject for speculation for some years There is at least some evidence, however, that the γ system is not a necessary part of the voluntary control of skeletal muscle (Evarts, 1967)

THE KNEE AND ANKLE JERKS

A sharp tap upon the patellar tendon, when the knee joint is semiflexed, stretches the quadriceps extensor muscle and causes it to contract Similarly a blow upon the tendo Achillis causes a quick contraction of the calf muscles These brief contractions or jerks, as well as those described below for the upper limb, are "fractional examples of the stretch reflex" and are not due to stimulation of the tendon but to stretching of the muscle, a stretch of 0 05 mm or less in $\frac{1}{20}$ sec , sufficient to elicit the response A voluntary action, such as clasping the hands together, reinforces the reflex and increases the force of the jerk The spinal center for the knee jerk in the human subject lies in the 2nd, 3rd, and 4th lumbar segments of the cord, it is innervated through the anterior crural nerve The center for the ankle jerk is situated in the 1st sacral segment, the peripheral nerve is the sciatic

Any condition, such as decerebration or injury to the descending motor pathways, which enhances the stretch reflexes increases the tendon jerks [1] They are abolished by an injury or disease involving the efferent or afferent limb of the reflex arc or the center itself (anterior horn cells) On account of its brief twitchlike character the knee jerk is sometimes spoken of as the "phasic reaction" of the stretch reflex The knee jerk is less affected by abnormal states, e g , spinal transection, anesthetics, circulatory failures, etc , than are the postural reactions In an animal such as the dog or rabbit, the knee jerk returns in a few minutes after spinal transection, in the monkey only after some days In man, though postural reflex activity is entirely lost and the muscles are quite flaccid, the knee jerk is elicitable in some degree within 3 weeks after a complete transverse lesion of the spinal cord

The smooth and steady character of the contractions brought about through the stretch reflexes concerned with the maintenance of posture is due to the asynchronous sensory impulses set up by the numerous stretch receptors and the resulting asynchronous reflex discharge of motor impulses to the muscles The muscle fibers are, therefore, never all re-

[1] When the electrical responses are recorded from the muscle of an animal during the elicitation of a tendon jerk, cessation of the action currents is found to occur during the actual contraction of the muscle This, the so-called "*silent period*," is probably due to the muscle spindles being relieved of stretch as the muscle shortens An additional factor is the synchronous nature of the discharge down the motoneurons, for the latter, being all excited in unison, pass also simultaneously into the subnormal phase

laxed nor all contracted at the same time The sharp contraction of the quadriceps characteristic of the knee jerk, on the contrary, is brought about by the discharge of a volley of synchronous impulses which causes the fibers of the muscle to contract in unison

Clonus Under certain conditions a muscle or group of muscles instead of contracting smoothly and continuously may do so rhythmically in a series of rapidly repeated movements or jerks Thus, in lesions of the central nervous system associated with hypertonus, sharp passive dorsiflexion at the ankle joint with maintenance of the foot in the dorsiflexed position by light pressure upon the sole, evokes a stretch reflex which consists of a series of rhythmical contractions of the stretched muscles (ankle clonus) The sudden dorsiflexion causes a sufficient number of stretch receptors to discharge a synchronous volley of impulses along the afferent nerve to the spinal centers and a synchronous efferent volley to be discharged to the muscles The continued stretch of the muscle caused by keeping the ankle in the dorsiflexed position sets up another synchronous volley as soon as the motoneurons have recovered each time from the subnormal phase of the preceding one Thus, the clonic movements continue so long as the muscles are kept upon the stretch Clonus can be evoked in a similar fashion in other situations It seems convenient to regard all such rhythmic activity as arising from feedback loops that oscillate because their normal damping mechanisms are not working properly (see also p 9-113)

SOME OTHER STRETCH REFLEXES (DEEP OR TENDON REFLEXES) OF CLINICAL IMPORTANCE

The *jaw jerk* Tapping the chin with the mouth partly open, and jaw supported, stretches the masseters which contract and jerk the jaw The reflex center is in the pons

The *biceps jerk* is elicited by a sharp tap upon the biceps tendon in front of the elbow joint, the response consists of a quick contraction of the biceps with flexion of the elbow The center for the reflex is situated in the 5th and 6th cervical segments of the cord, it is innervated through the musculocutaneous nerve

The *triceps jerk* is evoked by a blow upon the triceps muscle just above the olecranon process of the ulna, contraction of the muscle and extension of the elbow result The center for the response lies in the 6th and 7th cervical segments, the peripheral nerve is the musculospiral (radial)

The *supinator jerk* consists of contraction of the supinator muscle and flexion of the elbow, it follows a blow upon the styloid process of the radius The center lies in the 5th and 6th cervical segments of the cord, the peripheral nerve is the musculospiral

Rossolimo's reflex, which is seen with hyperactivity of the stretch reflexes in the lower extremity, consists of flexion of the toes, including the hallux, when the toes are flicked on their plantar surfaces A similar response (*Hoffmann's reflex*) which consists of a sudden flexion of the terminal phalanx of the thumb can be evoked by flicking the finger tips

5 / SUBCORTICAL MECHANISMS CONTROLLING POSTURE AND LOCOMOTION

CORTICAL VS SUBCORTICAL MECHANISMS

Neural mechanisms controlling movements of the body are extremely complex and as yet incompletely understood "Voluntary" movements[1] are dependent in primates (monkeys, apes, and man) upon the precentral motor cortex The same is not true for lower animals *Birds* and *reptiles* have practically no cerebral cortex (Ariens Kappers, 1929), and their well-organized movements are controlled by nuclear masses more or less comparable to the basal ganglia of the primate brain In higher animal forms such as *rodents* the cerebral cortex is present but of relatively little importance so far as muscular activity is concerned In the *carnivores*, e g , cat and dog, a specialized portion of the cerebral cortex that lies quite far forward (the sigmoid gyrus) functions as a motor cortex If it is stimulated electrically, movements can be produced in the contralateral extremities, and if the sigmoid gyrus is removed a transitory contralateral paralysis ensues However, the cerebral cortex is not essential for useful movement of the skeletal musculature It can be removed from both sides with only a temporary paralysis, the animal will recover the ability to sit, stand, walk, or run (Bard and Macht, 1958) In *primates* the situation is quite different Here the cerebral cortex is much more important even though there exists a considerable difference between the various animals If one removes the precentral motor cortex, i e , the gyrus ahead of the central sulcus, or even the entire cortex from one cerebral hemisphere in a monkey, a complete paralysis of the opposite side of the face and of the opposite arm and leg will result Useful movement will soon begin to return and in a few weeks the animal will be running about climbing the walls of his cage and hopping about on his trapeze in an agile fashion, although a partial paralysis of the involved arm and leg will be obvious The ape, too, will recover, though not so completely as the monkey, whereas removal of the precentral motor cortex in *man* will result in a contralateral paralysis which, though it will improve, will always be severely disabling After such an operation a man will become able to walk, although with a limping gait dragging and circumducting his leg He will never recover useful movement in his upper extremity and will probably have no movement at all in his hand and fingers

The recovery in primates following removal of the precentral motor cortex is due almost entirely to ipsilateral innervation from the intact cerebral hemisphere, for if the remaining precentral motor cortex is removed a severe and enduring paralysis *in all four extremities* is the immediate result It is true that if the cortex is removed piecemeal in several operations over months of time and if the animal is given very special care occasionally it is possible to produce a bilaterally decorticate monkey that is able to make a few awkward but very limited voluntary movements At best such an animal is almost completely disabled In most instances he is totally paralyzed except for a few useless sterotyped grasping movements In view of the demonstrably greater importance of the precentral motor cortex in man as compared with the motor cortex of cats it is obvious that in the human being the production of useful voluntary movements is dependent upon this important area of the cerebral cortex It is likewise evident that the subcortical centers (basal ganglia, red nucleus, substantia nigra, reticular formation, cerebellum, and spinal cord) are important in

[1] A "voluntary" movement is one that I believe I could make if I wanted to

the production of well-coordinated, useful muscular activity, but in man these centers cannot function adequately in the absence of the precentral motor cortex

CORTICAL PROJECTIONS TO LOWER MECHANISMS

The precentral motor cortex gives rise to corticospinal fibers which arise from the precentral gyrus and descend to the anterior gray horns of the spinal cord (Fig 9 75) These fibers are concerned with voluntary muscular activity and primarily with delicate, precise, well-coordinated movements of the distal parts of the extremities, particularly the digits The relationship of the corticospinal fibers which arise in the parietal cortex to voluntary muscular activity is unknown It is certain, however, that this parietal component of the corticospinal system is not capable of producing useful coordinated movements independent of the precentral motor cortex

The precentral motor cortex gives rise also to many other descending fibers with motor functions There are fibers to the basal ganglia, thalamus, red nucleus, substantia nigra, the pontine nuclei, the inferior olivary complex and the reticular formation These, too, are concerned with the production of voluntary muscular activity In the absence of the corticospinal tract such movement is apt to be cruder and less delicate but still useful Exactly which of these many fiber systems—corticocaudate, corticopallidal, corticonigral, corticopontine, etc —is concerned in the production of voluntary muscular activity is unknown

These neural mechanisms are also concerned with other functions of great importance in the organization of muscular activity These include the control by inhibition and facilitation of *1)* the various postural reflexes, *2)* of various automatic and associated movements, such as swinging of the arms when walking, and *3)* of various visceral and vasomotor activities such as respiratory movements, blood pressure, pulse rate, the vascular bed, gastrointestinal motility, etc , that accompany movements of other parts of the body

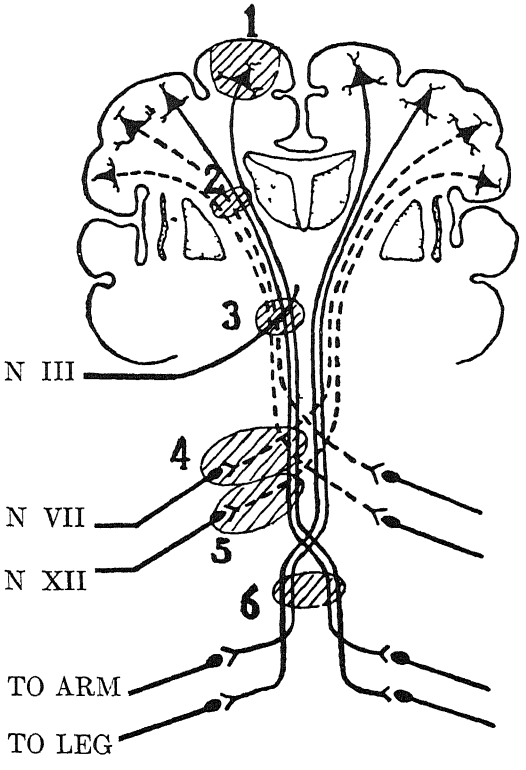

Fig 9 75 Diagram illustrating the clinical signs that follow typical lesions of the central nervous system *1)* Lesion of cerebral cortex causes monoplegia or hemiplegia depending upon its extent *2)* Lesion in internal capsule may cause hemiplegia *3)* Lesion of midbrain may involve descending motor fibers to opposite side of body and an ipsilateral eye muscle nucleus *4)* or *5)* Lesion in pons or medulla has results similar to location 3 but involving other cranial nerves *6)* Transection of spinal cord causes paraplegia

MECHANISMS OF POSTURE

Tone of Skeletal Muscle

As a result chiefly of the work of the Sherrington school the word "tone" or "tonus" as applied to skeletal muscle acquired a specific, technical meaning Muscle tone is the steady reflex contraction of the muscles concerned in maintaining the posture characteristic of a given animal species Tonus has its basis in the stretch reflexes, and in a standing animal its seat is therefore mainly in the *antigravity muscles* In most mammals these are extensor muscles, the muscles that show an exaggeration of tone following decerebration

In man the antigravity muscles and consequently those which exhibit the greatest degree of tone are the retractors of the neck, the elevators of the jaw (masseters), the supraspinatus, the extensors of the back, the ventral muscles of the abdominal wall (probably), and the extensors of the knee and ankle (vastocru-

reus, gastrocnemius, and soleus) When these muscles are completely relaxed, as in an unconscious person, the body collapses In the healthy conscious person, stretch reflexes are largely instrumental in preventing this occurrence

Though the fundamental basis of tonus in voluntary muscle is the myotatic reflex centered in the spinal cord, the tonic state is influenced profoundly by higher centers Impulses from labyrinthine and neck muscle receptors exert an influence upon a background of tonus established through lower spinal centers Similarly, pathways from cerebellar, midbrain, and cerebral neurons convey impulses which, impinging upon the final common path, are capable of altering the degree of tonus, or effecting finer adjustments in the tonic state and of maintaining its normal distribution between groups of muscles (Fig 9 82, p 9-108) The tone of a given group of muscles may also be influenced through the spinal centers by impulses arising in other muscle groups (e g , neck muscles and the muscles of the digits, ankle, and wrist, as in the positive supporting reaction) and in skin receptors

When the spinal cord is separated from higher centers there is an a-reflexic state of muscular flaccidity Gradually this gives way to a state of hyperreflexia The extensor tone, however, never is as pronounced as in decerebrate rigidity, whereas the flexor reflexes are more active

A feature of tonic contraction is its economy in the expenditure of energy Posture is maintained for long periods with little or no evidence of fatigue Examples are found in decerebrate rigidity, in the maintained closure of the jaws, standing or sitting in the normal person, and in the clasping reflex of the frog The economy of energy is possible because different groups of muscle fibers contract in relays, only a proportion of the total number of fiber groups of the muscle being active at any moment Thus, active fiber groups mingled with inactive groups are scattered throughout the muscle The alternating periods of rest and activity of the muscle groups explains the ability of the tonic contraction to be maintained for so long without showing fatigue

RED AND WHITE MUSCLE

The skeletal muscles of many animals, e g , birds, rabbit, cat, etc , can be clearly divided into two types, *a) red or dark,* and *b) white or pale* (Creed et al , 1932) Of the two, the red muscles are composed of smaller fibers having a granular and more opaque appearance, possessing more distinct longitudinal striations but less pronounced cross striations, and containing a larger proportion of sarcoplasm These fibers contract more slowly, fatigue less readily, and are tentanized at a slower rate of stimulation than are the pale fibers The white or *pale* fibers are translucent, show prominent cross striations and a small quantity of sarcoplasm Those muscles which execute rapid movements are usually, though not invariably, of the pale variety, whereas the slower movements are carried out chiefly by the dark muscles It is probable that all muscles are a mixture of the two types of fiber, but that in some the red, in others the pale type, predominates

Experimental Preparations for Study of Posture

THE SPINAL STATE

Transection of the cord produces an immediate flaccid paralysis of the muscles below the point of section Immediately after section in the lower cervical region the limbs hang limply, the muscles being quite toneless The stretch reflexes and other extensor responses cannot be elicited and the knee jerk is abolished The blood pressure falls and vascular and visceral reflexes are unobtainable This condition is called *spinal shock* Its duration varies from species to species The higher the position of the animal in the phylogenetic scale the more profound is the shock and the slower is the recovery In the frog the duration of spinal shock is brief, a few seconds In the rabbit, the knee jerk returns within a few minutes, in the cat within an hour, and in the dog somewhat more slowly In the monkey it does not reappear for several days Other extensor reflexes remain in abeyance for a much longer time In the cat and dog the picture immediately following spinal transection is different from that seen after decerebration The extensor stretch reflexes are less active while the flexor responses to nociceptive stimuli are more easily elicited Consequently, if the spinal cord of a decerebrate preparation is sectioned, the exaggerated extensor tone is replaced (below the section) by an imbalance in the sense of increased flexor tone

Spinal shock also follows section through the

medulla below the vestibular nuclei (*decapitate preparation*)

In the cat and dog recovery from spinal shock gradually takes place in a few days The blood pressure is restored to normal and the vascular reflexes can again be obtained The reactions of the extensor muscles return, and the animal is able, though imperfectly and very briefly to support the weight of the body when placed upon its feet (They cannot "stand" as does a normal animal, of course, because spinal motor mechanisms are cut off from those in the brainstem that are required for postural adjustments See below)

Cats, dogs, and rats that have recovered from spinal shock exhibit neural reactions that provide information about the function of spinal mechanisms For example, they eat normally, and digestion is not impaired Defecation is at first seemingly uncontrolled, with diarrhea and/or constipation, but later acquires a reflex character with stools that are formed normally Urination has a similar course, with first of all a retention of urine in the bladder that can be relieved only by artificial means such as catheterization or manual expression After a few days, however, the bladder empties periodically on a reflex basis

Spinal animals also exhibit reflex performance that is surprisingly complex Two notable examples are the rhythmic movements of the scratch reflex—an intersegmental reflex in which the hind leg moves rhythmically in response to stimulation of the skin over the shoulder—and stepping or the "mark time" reflex, in which the two hind limbs alternately extend and flex in movements like those that produce locomotion

Explanation of Spinal Shock. Spinal shock is attributed to the removal of impulses which in the intact animal descend from higher centers to reinforce the spinal centers That it is due to this and not simply to an inhibitory effect of the local injury itself seems clear from the fact that after an animal has recovered from spinal shock, a second transection made behind (lower than the original one) does not cause a return of the shock state In *the cat and dog* the flexor reflexes are evidently dependent only to a minor extent upon the higher centers, since they are capable of being executed by the spinal centers alone They are also seen in their most exaggerated form in animals or human beings with a complete transection of the spinal cord The fact that the extensor stretch reflexes are less active in the spinal animal is due to the loss of facilitatory impulses from the reticular formation and the vestibular nuclei Recovery of reflex activity following transection of the spinal cord is in considerable measure dependent upon the condition of the animal or patient Infection or impaired nutrition greatly retard recovery

DECEREBRATE RIGIDITY

This is the term applied to the sustained contraction of the extensor muscles which supervenes upon transection of the brain stem at any level between the superior colliculi and the vestibular nuclei [2] It was first studied and described in detail by Sherrington (1906) The animal assumes a characteristic attitude with limbs stiffly extended, head retracted, jaws closed, and tail horizontal or erect When placed upon its feet the limbs support the weight of the body The position is a *caricature* of the normal standing position The knee jerk and other stretch reflexes are exaggerated The righting reflexes are abolished, tonic neck and labyrinthine reflexes are retained

In some instances there is increased reflex excitability of the flexor muscles as well, but the characteristic feature of decerebrate rigidity is the tonic contraction of the muscles which maintain the posture of the body against gravity, the *antigravity muscles* It may be pointed out that in the frog whose natural posture is squatting with flexed thighs, legs, and arms, it is the flexor muscles which are the site of decerebrate rigidity Also in the sloth, whose habit it is to remain for long periods suspended from a tree branch, flexor rigidity is the characteristic result of decerebration In the pigeon the flexor muscles which maintain the resting (folded) position of the wing exhibit rigidity, and in the ape the muscles which hold the elbow semiflexed when the body is erect show increased tone In man abolition of the function of the cerebral motor cortex results in a state of increased tone in the flexors of the arms and in the extensors in the lower extremities, whereas decerebration at the mesencephalic level is associated with extensor spasticity in all four extremities

Tonic Labyrinthine and Neck Reflexes in

[2] Decerebration can also be produced by tying the common carotids and the basilar artery at the center of the pons and thereby depriving the forebrain of its blood supply

the Decerebrate Preparation. Labyrinthine proprioceptors are responsible for the tone of the neck extensors, consequently, after destruction of the labyrinths in the decerebrate preparation the head is no longer held erect but falls into the fully flexed position (Fig 9 76) The rigidity in the forelimbs in turn is maintained through proprioceptive reflexes initiated in the extended neck muscles as well as directly through labyrinthine reflexes (Fig 9 77) After labyrinthectomy, therefore, the flexed position assumed by the head sets up proprioceptive impulses from the neck muscles which lead to a reduction in the extensor tone of the forelimbs, these then become strongly flexed upon the chest If the neck muscles of the labrinthectomized animal are deafferented, movements of the head are without effect upon the extensor muscles of either fore or hind limbs

Lengthening and Shortening Reactions. Attempts at passive flexion of the extended limb of the decerebrate (or chronic spinal) preparation are met by considerable resistance If the force is increased beyond a certain point the stretch reflex (upon which the resistance depends) is inhibited and the limb gives way suddenly (*clasp-knife effect*) It may then be easily flexed to any degree and remains in the new position The elongation of the extensor muscles which permits the flexion of the limb is called the *lengthening reaction* If the limb is then moved again into the extended position the extensor muscle shortens adaptively, and again resists the limb being bent This is the *shortening reaction* These reactions give the muscles a certain plastic quality The giving way of the extensor contraction in the lengthening reaction is ascribed to inhibitory impulses from the Golgi tendon organs that are set up when the stretch stimulus reaches a certain intensity With inhibition of the forcibly flexed knee extensor, the knee extensor of the opposite leg is excited, this is known as *Phillipson's reflex*, a special instance of the principle of reciprocal innervation

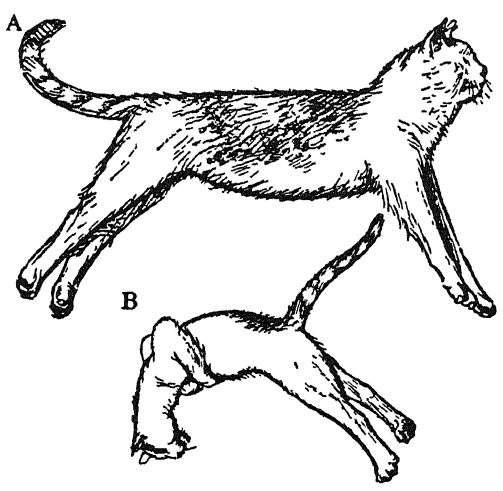

Fig 9 76 *A* Posture of cat following midcollicular decerebration there is overactivity of all the antigravity muscles *B* Decerebrate cat following labyrinthectomy the head is no longer supported against gravity and flexion of the neck leads to reflex inhibition of extensors of fore limbs

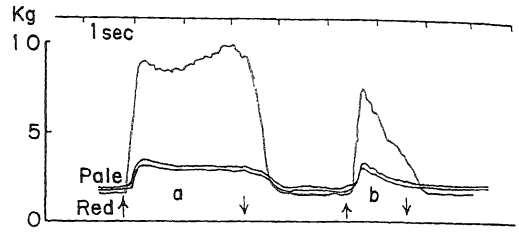

Fig 9 77 Influence of neck reflexes on stretch reflex in decerebrate preparation With triceps muscle stretched to induce reflex in both heads (red muscle *upper line* pale muscle *lower tracing*) the force of contraction is increased when neck is dorsiflexed and decreased with ventriflexion (*arrows*) (Creed et al 1932)

Mechanisms Responsible for Decerebrate Rigidity Decerebrate rigidity is quite evidently a "release" phenomenon, brought about by the removal of inhibitory mechanisms that lie ahead of the plane of section and that normally inhibit the neurons that now cause the rigidity (This is the inverse of the concept that spinal shock is a result of loss of rostral facilitatory mechanisms) The level of the neurons that induce the extensor rigidity can be specified, in cats it is the level of the pontile and upper medullary tegmentum If the plane of decerebration is at or above the rostral limit of the mesencephalon, little or no rigidity occurs, this indicates that the inhibitory mechanism lies in the rostral mesencephalic tegmentum Consequently, if the first section is made superior to the mesencephalon, and then after some minutes sections are made at progressively lower levels, the animal is at first not rigid but becomes so when the rostral mesencephalon is removed With the lower cuts the rigidity may increase to a maximum, and

then decrease again finally to disappear when the plane of section is at the lower border of the pons As noted in section 6, and in chapter 7 of this section, typical changes in pattern of respiration accompany these changes in posture

In a cat made decerebrate by a midcollicular section, the cerebellum has a curious relationship to the rigid state When an electrical stimulus is applied to the cortex of the anterior lobe, the rigidity is decreased, if this portion of the cerebellum is ablated, the rigidity increases For this particular mechanism, at least, this part of the cerebellum seems to have an inhibitory function analogous to that of the rostral mesencephalic tegmentum

Granit (1955) has shown that the brainstem mechanism that produces the rigidity does so by way of the stretch reflexes of antigravity muscles It facilitates the strength of the intrinsic control of muscle stretch receptors by activating the γ motor fibers This makes the receptors overly sensitive to stretch, intensifies their stretch reflexes, and leads to the decerebrate state The factor that determines that it is the extensor and not the flexor muscles that become hyperactive must be assumed to be the way the reticular facilitatory mechanism is organized Both extensor and flexor muscles have the same kind of control system from the level of the medulla down through spinal cord and out to the muscles The fact that removal of higher levels leads to only extensor rigidity, however, indicates that it is the extensor components of the reticular-spinal system that are usually subject to powerful inhibition from above The components that are so inhibited seem to include the reticular formation at the pontile level, the vestibular nuclei, and the central nuclei of the cerebellum These latter nuclei, in fact, can be regarded functionally as displaced components of the bulbar facilitatory system

From the outline given in chapter 2, it is apparent that there is no lack of descending tracts that might impose a tonic inhibition upon these tegmental and cerebellar nuclei The corticobulbar and corticopontile fibers, however, probably do not need to be considered in this connection, inasmuch as removal of the cerebral cortex of a cat leads to little evidence of extensor rigidity Furthermore, the lack of rigidity following high mesencephalic section also argues against the significance of telencephalic structures The most plausable conclusion, for the cat at least, is that both the inhibitory and excitatory mechanisms for the rigidity reside in the brainstem tegmentum and cerebellum The principal collection of cells found at the level of the critical plane of section is the red nucleus (Fig 9 78) When it retains its connections with brainstem and cerebellum, there is little rigidity, when the plane of section is below this nucleus, ridigity is marked If the inhibition normally exerted upon extensor reflexes does, in fact, arise in the complex of systems that includes the inferior olive, the Purkinje cells and nuclei of the cerebellum, and the red nucleus, this might explain why maximal rigidity follows concurrent removal of red nucleus and anterior cerebellar cortex

One other significant feature of the decerebrate state should be noted, namely, the evidence it offers for opposing facilitatory and inhibitory mechanisms in the brainstem (Fig 9 79) That such opposed mechanisms are almost ubiquitous in control systems will become evident as they are more fully described In general, the two types of components may lie together at any level of the neuroaxis, but occasionally they are at different levels as in the case of decerebrate rigidity, and also the expiratory and inspiratory mechanisms of the medullary respiratory system Longitudinally, these systems are organized so that there is increasing complexity of function at progressively higher levels of the nervous system

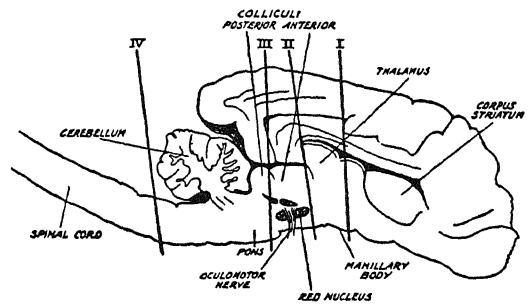

Fig 9 78 Levels of section through the brain of cat to illustrate typical results *I) Thalamic animal* Righting tonic labyrinthine and neck reflexes are retained little change in muscle tone *II) High decerebration* Minimal decerebrate rigidity *III) Midcollicular decerebration* Extensor rigidity may be maximal If vagi are cut, animal may show apneusis *IV) Medullary or decapitate animal* Condition depends completely upon level of section Usually there is no rigidity respiration may be gasping in type

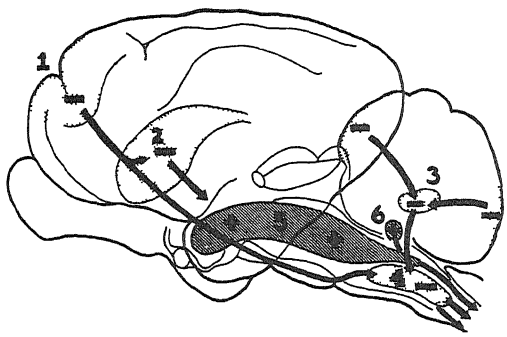

Fig 9 79 Outline drawing of structures in cat s brainstem in cerebellum and cerebral cortex Stimulation of regions marked + facilitates spinal reflex activity whereas regions marked – inhibit reflex responses (Lindsley et al 1950)

Thus, at spinal levels they control through opposing actions the strength of reflex responses, at the medullary level they evoke inspiration or expiration, raise or lower the blood pressure, accelerate or slow the heart, and strengthen or weaken the tone of antigravity muscles In the hypothalamus they raise or lower body temperature, and increase or decrease water and food intake Of these examples, however, posture is in many respects the one easiest to analyze, and how it is controlled may be used as a guide in study of the other systems

"THALAMIC ANIMAL

It is relatively easy to perform an operation in which most of the cerebral cortex is removed on both sides, with most of the white matter beneath it and accessible portions of the basal ganglia What remains is the diencephalon, together with variable amounts of the basal ganglia that were left behind The resulting preparation has been called a "thalamic" animal This name is misleading, because it is inconceivable that the thalamus under these conditions could have anything approaching its normal function Those thalamic nucleic most directly related to cerebral cortex must be seriously affected by the operation, and neurons sending their processes to the cortex can scarcely retain normal function after their processes are cut Consequently, no one knows just which subcortical structures are capable of activity, nor at what level in the neuroaxis the behavior exhibited by these animals may originate Nevertheless, because they can be prepared and maintained relatively easily, their neurological condition is of some interest

These animals retain their righting reflexes and can regulate their body temperature They are also capable of carrying out coordinated reflex acts and show, often to an exaggerated degree, reactions which are associated in the intact animal with the emotional states of fright and of anger Such reactions, termed pseudoaffective, are also exhibited by an animal whose cortex alone has been ablated, the condition known as "sham rage " In contrast to the decerebrate animal, the distribution of muscular tone in the thalamic cat or dog shows little departure from the normal, though pronounced extensor rigidity becomes evident when the animal is held suspended in midair

Primates, on the contrary, are usually unable to walk after bilateral decortication, and there are profound alterations in the muscular tone of the limbs The animal generally assumes a characteristic attitude When lying upon its side the limbs of the under part of the body are extended and the uppermost limbs flexed (Fig 9 80) The uppermost limbs show a pronounced grasp reflex Turning the animal on to its opposite side reverses the picture The limbs which were underneath and extended are now flexed and show the grasp reflex, while the limbs previously uppermost, being now underneath, are extended Righting reflexes (except those dependent upon vision) and the tonic labyrinthine and neck reflexes of Magnus and de Kleijn are shown in a striking fashion Fig 9 81

If the extirpation of the cerebral cortex of a monkey is carried out piecemeal over a considerable period of time, and if the animal is

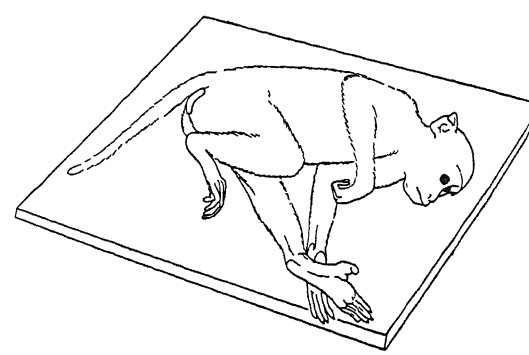

Fig 9 80 Posture of decorticate monkey when it is lying on its left side The two lower limbs are extended the upper ones are flexed

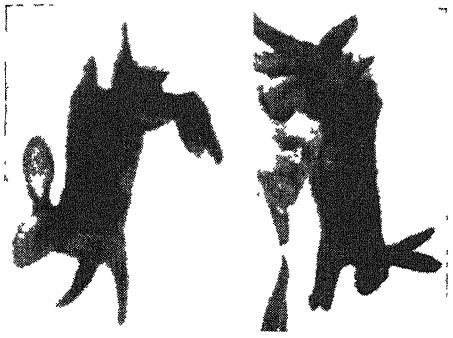

Fig 9 81 Posture of decorticate rabbit suspended from a hand grasping the pelvis *A* The labyrinths are intact and there is righting of the head and neck with postural response in forelimbs *B* After labyrinthectomy the head and forelimbs hang limp (Magnus 1926)

given meticulous care as to nutrition and manipulation of its extremities, it may be able to stand briefly and awkwardly and may even take a few steps, but in general such an animal is quite disabled The disability is much more profound than that seen in a decorticate or thalamic cat

Reflex Maintenance of Posture

By observing cats and rabbits after operations upon the central nervous system, Rudolph Magnus (1926) and A de Kleijn (1923) of Utrecht were able to describe the responses through which posture is maintained and righting achieved (Their papers are in English) They classified these responses according to what they do for the animal, whether righting, change in posture, movement of the eyes, etc , and also in terms of the sensory organs from which the responses originate The most important of these sense organs include *a*) the visual system, *b*) the semicircular canals, utricle, and saccule of the labyrinth, *c*) stretch receptors in muscles and ligaments of neck muscles and joints, *d*) pressure receptors in toe pads and in other surfaces of the body, and *e*) stretch receptors of muscles of the limbs The function of these responses is to govern the orientation of the head in space, the position of the head and eyes in relation to the trunk, and the position of the limbs and eyes in relation to position of the head They aid in maintaining the orientation of the body in relation to gravity, as well as restoring the body to an upright position when its posture has been disturbed Some of these phenomena are true reflexes, whereas for others the word, response, is more appropriate The nature of the response usually is evident from the name that has been given to it

A) LOCAL AND SEGMENTAL STATIC REACTIONS

1) Positive Supporting Reaction simultaneous reflex contraction of both extensor and flexor muscles that converts the limbs into rigid pillars It is initiated by stimuli from pressure receptors, e g , in sole of foot, and proprioceptors in muscles that would be stretched if the leg collapsed

2) Negative Supporting Reaction relaxation that permits the limb to be moved to a new position It is initiated by passive flexion of the limb

3) Segmental Static Reactions flexion and crossed extension reflexes, are described in chapter 4

B) GENERAL STATIC REACTIONS

1) Statotonic or Attitudinal Reflexes

a) *Tonic Labyrinthine and Tonic Neck Reflexes Acting upon the Limbs* influence tone of skeletal muscles and maintain the different parts of the body in an attitude appropriate to a given position of the head Receptors are in the labyrinth (utricle and saccule) and in muscles, tendons and ligaments of the neck In an animal on all fours the labyrinthine effect is to increase the extensor tone in the muscles of all four limbs when the head is strongly extended, and to decrease the tone when the head is flexed The tonic neck reflexes, by contrast, evoke flexion of the fore limbs and extension of the hind limbs when the neck is flexed towards the sternum, extension (dorsiflexion) of the neck produces the converse picture Rotation of the head causes increased tone in the fore- and hindlimbs on the side of the body toward which the jaw is rotated, and reduces the extensor tone in the opposite limbs. In man this is the classic pose of a boxer.

b) *Tonic Labyrinthine and Tonic Cervical Reflexes Acting upon the Eyes* tonic effects upon eye muscles, anal-

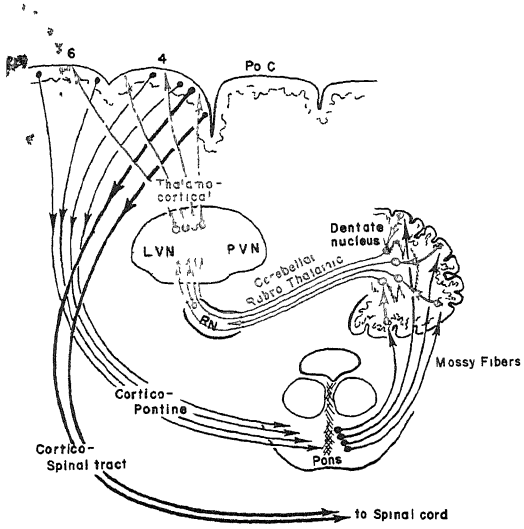

Fig 9 82 Pathways by which the cerebral cortex pons cerebellum red nucleus and thalamus are interconnected Interruption of this circuit between cerebellum and thalamus may cause an intention tremor

produces smooth movement becomes oscillatory when one component, the cerebellum, is disconnected But the subsequent removal of another component, the premotor cortex, decreases the oscillations Perhaps this second operation decreases the power transmitted through the system, or at least through that part that previously evoked the oscillation This topic is considered later in this chapter in connection with rhythmic activity in the central nervous system

The deficiencies in motor movement after removal of the cerebellum include a prolongation of the latency of response of both contraction and relaxation of muscles, together with both increase and decrease in strength of individual muscle contractions All of these effects represent dysfunction of the corticospinal systems (including their γ motor portions), and have been utilized for a recent hypothesis as to how the cerebellum functions (Blomfield and Marr, 1970) Eccles et al (1971) have suggested that the key to cerebellar function is found in the distribution of connections to and from the Purkinje cells

There are many experiments that suggest that the influence of the cerebellum on the corticospinal system is facilitatory, whereas others imply an inhibitory effect. The central nuclei of the cerebellum apparently belong functionally to the bulbar facilitatory system, as noted earlier, so that stimulation strong enough to activate them will increase muscle tone and strength, especially in the extensor muscles of a cat The cortex by way of the Purkinje cell projection, by contrast, inhibits central nuclei and Deiter's nucleus of the brainstem (Fig 9 83) Cortical stimulation alone, therefore, should decrease muscle tone, especially in the extensors The discovery of these two opposed types of actions should lead eventually to a better understanding of data from stimulation experiments At the present time such data are contradictory, perhaps because stimuli applied to the cortex would not produce any apparent effect because the resulting inhibition could be observed only against a background of antecedent activity

FLOCCULONODULAR LOBE AND OTHER PARTS

Through its vestibular connections the flocculonodular lobe is concerned with equilibratory function, severe disturbances of balance resulting from its ablation Removal of this lobe in monkeys, or of the nodule and part of the uvula, is followed by pronounced disturbances of balance In man a lesion of this part of the vermis is also associated with disturbances of equilibrium Removal of the *nodule* alone in monkeys is followed by oscillation of the head and neck (and, in some instances of the whole trunk) falling backwards and an unsteady gait with the extremities spread widely apart to provide a broader and thus more certain base Ablation of the nodule in dogs confers immunity to motion sickness Removal

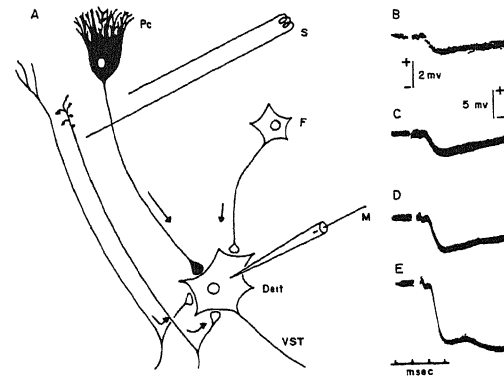

Fig 9 83 Demonstration of inhibitory action of a Purkinje cell upon a cell in a vestibular nucleus (Deiters) *F* is an excitatory cell from fastigial nucleus, *VST* is vestibulospinal tract *S* is stimulating electrode *M* is the intracellular, recording electrode The records *B–E* on the right show the development and course of the inhibitory postsynaptic potentials (*IPSP*) (Eccles 1967)

of other regions of the cerebellum or of the cerebral cortex does not have this type of protective action

The functions of the *uvula* are largely obscure, its destruction alone is followed by some transient disturbance of equilibrium Very little is known of the function of the *pyramid*, although it appears to be concerned in some way with vision or eye movement Its excision causes no defect of balance Ablation of the pyramid in the monkey results in an inability to halt its forward progression in time to prevent it from crashing into some obstacle Faradic stimulation of the pyramid elicits an upward movement of the eyes, and Fulton argued from this fact and the preceding observation in favor of the possibility of the pyramid's being concerned in some way with the integration of proprioceptive impulses essential in judging distance

Basal Ganglia

The many connections and interrelations the basal ganglia have with other parts of the somatic motor systems (chap 2) suggest that they must participate in a considerable variety of motor functions (Fig 9 84) What is known of their properties can be summarized in two statements, as follows *1*) they stabilize or "damp" movements that otherwise would be rhythmic or oscillatory, *2*) especially in lower animals but presumably also in man they have the capacity to initiate movement

It has been difficult to attribute specific functions to individual ganglia, in part because lesions created experimentally usually do not produce obvious deficits Perhaps this is because the requisite imagination and insight have not yet been brought to bear on the problem of testing the performance of the animals If one is to disclose an input-output relationship, the input must be appropriate for the mechanism being analyzed

DYSFUNCTION OF BASAL GANGLIA

Information about functions of the basal ganglia has come principally from observation of patients with lesions in these structures Three types of lesions are typical, as follows

1) Lesions found in the putamen of the lentiform nucleus as a result of copper intoxication in Wilson's disease—hepatolenticular degeneration—cause tremor and rigidity

2) Lesions found in the substantia nigra following manganese intoxication cause symptoms of Parkinson's disease (paralysis agitans), as described under 3)

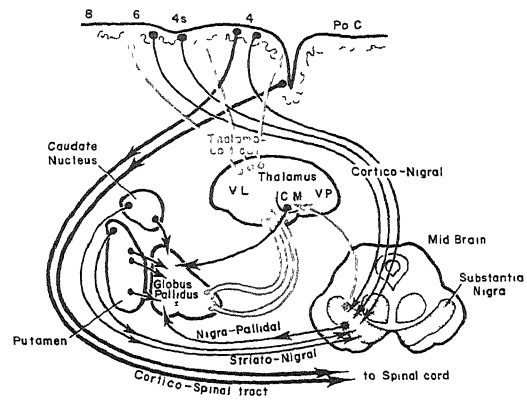

Fig 9 84 Portrayal of some of the better understood interconnections of the basal ganglia brainstem thalamus and cerebral cortex

3) Lesions that remain following encephalitis, and that are believed to occur also in patients with cerebral vascular disease, are responsible for paralysis agitans They involve the globus pallidus and substantia nigra, with depigmentation of the latter because of a failure of melanin accumulation

In addition to these three, other lesions may occur as a result of vascular disease, infections, or the growth of tumors

The symptoms of paralysis agitans include both slowing and weakening of somatic motor movements, loss of "associated" movements, for example in walking (see later), tremor of postural mechanisms, rigidity to passive manipulation of limbs, and an apparent dulling of emotional responses The tremor is known as a *tremor at rest,* it involves typically the muscles of the neck and upper limbs By contrast, the tremor that accompanies voluntary movement in patients with lesions of the cerebellum or its projection to the lateral ventral nucleus of the thalamus is an *intention tremor* Other symptoms associated with disease of the basal ganglia include two forms of spontaneous and involuntary movements, *chorea* in which the movements are quick and jerky, although apparently coordinated, and *athetosis* where they are slow, sinuous and writhing, and involve particularly the hands and forearms.

CONTROL FUNCTIONS

Although it has been repeatedly said that there is no localization of function, somato-

topic or otherwise, in the basal ganglia, clinical experience leaves no doubt that this statement is untrue As noted above, disease in different parts of the basal ganglia gives rise to vastly different clinical pictures Destruction at any point in the dentatorubrothalamic projection (Fig 9 82) causes an intention tremor Lesions of the substantia nigra and globus pallidus are associated with parkinsonism and a tremor at rest Destruction of the caudate nucleus and putamen is seen in patients with choreoathetosis Obviously there must be some functional differences between these various nuclei Every clinical neurologist is aware of how the tremor of parkinsonism may begin in the head and neck, or in the foot, or in a finger, and then later gradually spread to other parts of the body on the same or opposite side Obviously there is somatotopic localization in the basal ganglia in man, otherwise such localized manifestations of disease would not be possible

Voluntary Muscular Activity. For years it was supposed that voluntary muscular activity originates exclusively in the corticospinal system It is now obvious that that is incorrect, at least in species up to and including carnivores (see p 9-98) It is true, however, that in primates the situation is quite different Does this mean that in primates the basal ganglia and other subcortical centers have lost their ability to produce useful voluntary movements? This seems unlikely, but it does appear that they have lost their ability to produce such movements in the absence of the precentral motor cortex It may be that when the cortex of a primate is removed the basal ganglia are left in a hypoactive condition analogous to spinal shock, and thus are incapable of initiating movement If, on the contrary, these ganglia become hyperexcitable (as in dopa therapy, see below), then movement is generated on an involuntary basis

Reflex Muscular Activity. Rigidity is one of the characteristics of disease of the basal ganglia, notably Parkinson's *paralysis agitans* Clinicians frequently attempt to make a sharp distinction between the rigidity of diseases of the basal ganglia and the spasticity associated with decerebration and capsular hemiplegia However, the differences appear to be rather superficial As Fulton (see 1949) and his coworkers were the first to emphasize, both result from the loss of supraspinal inhibition which is not concerned with the corticospinal fibers Furthermore, the rigidity of paralysis agitans, like the spasticity of decerebration, is greatly diminished by interrupting afferent impulses from the involved muscle to the spinal cord This demonstrates that both rigidity and spasticity result primarily from activity of the local, spinal reflex arc which is released to hyperactivity by removal of descending, inhibitory influences Thus, it appears likely that the basal ganglia as well as the precentral motor cortex, area 4s and the bulbar reticular formation, exert an inhibitory influence over the spinal reflexes which control the muscular activity responsible for posture and reflex standing Clinical observations that lesions in the globus pallidus produced surgically in the treatment of various diseases result in the reduction of rigidity indicate the possibility that the basal ganglia exert an excitatory as well as an inhibitory influence upon the spinal reflex mechanism responsible for rigidity However, the physiological explanation of these clinical observations is as yet unknown This serves further to emphasize our ignorance in this field

Automatic Associated Movements. One thing that characterizes parkinsonism perhaps even more than tremor or rigidity is the loss of automatic associated movements Commonly this term is regarded as indicating only the swinging of the arms in walking—a type of movement which is abolished by various destructive lesions in the precentral motor cortex, in the cerebellum, as well as in the substantia nigra and globus pallidus in parkinsonism However, in parkinsonism far more is lost than automatic swinging of the arms There is a general poverty of movement The loss of expressional movements of the face results in the familiar masklike face There is also a generalized loss of movements throughout the body so that the victim is described as being "statuesque " It thus appears that the basal ganglia are responsible for a wide variety of automatic and associated movements

CHEMICAL TRANSMISSION

Further understanding of the performance of two of the basal ganglia, the substantia nigra and globus pallidus, has come from recent success in relieving the symptoms of patients with parkinsonism (Figs 9 85 and 9 86) by administration of the amino acid, L-dihydroxy-

phenylalanine (dopa) (Cotzias, et al, 1967, 1969) The efficacy of this amino acid in counteracting these symptoms indicates that its derivative, dopamine (dihydroxyphenylethylamine), produced in the nervous system by the enzyme dopa decarboxylase, is an essential transmitter somewhere in this system (Fig 9 87) Two earlier observations had suggested that this type of transmission might be involved First, dopamine was identified in this part of the brain by Carlson and his colleagues (1958), who found also that the concentration was lowered following administration of the drug, reserpine When dopamine was then given after reserpine it did not enter the brain to restore the usual levels, indicating that it cannot pass across the capillary-meningeal boundary that is called the "blood-brain barrier" (Carlson et al, 1957) The administration of dopa, by contrast, did restore the dopamine level in the brain via the decarboxylation reaction mentioned above

Second, Hornykiewicz (1963) found reduced concentrations of dopamine in the substantia nigra of patients with Parkinson's disease This observation is believed to have some as yet unexplained relation to the depigmentation of this structure in these patients Melanin, the pigment, is likewise derived in the body from dopa The metabolic significance of the pigment in these cells, however, is not clear, nor is the reason for the concurrent deficiencies of melanin and dopamine

In the course of treatment of these patients, two other phenomena were noted that are of neurophysiological significance First, inasmuch as most of the dopa given was distributed throughout the rest of the body, (in addition to the fraction that entered the brain,) there was a generalized elevation of dopamine levels as a result of decarboxylation in other tissues, for example, the liver This led to symptoms of dopamine intoxication, and in some cases necessitated a reduction in dose of dopa administered The intoxication was especially marked in early experiments where the racemic or D,L form of the amino acid was the only form available in the quantities needed, when the L form became available the total dose could be cut in half and general symptoms of intoxication were less troublesome Cotzias has suggested (1969) that it may prove feasible to block the decarboxylation reaction in peripheral tissues by giving a blocking drug that, itself, cannot enter the brain.

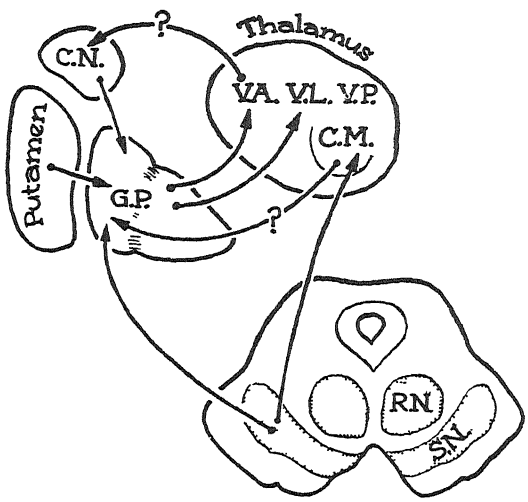

Fig 9 87 Projections from substantia nigra as significant components of interrelationships of basal ganglia Compare with fig 9 84

Second, another type of undesired side effect of the dopa treatment was involuntary movements that included myoclonus, athetosis, and chorea The therapy that relieved the tremor and rigidity, therefore, and that created a sense of "awakening" in the patients, also led to movements that presumably were generated in the basal ganglia

RHYTHMIC MECHANISMS

A significant feature of the involuntary movements associated with disease of the basal ganglia or cerebellum is repetition Steadiness of *a*) normal *posture* is replaced by a tremor at rest, smoothness of *b*) *movement* is obscured by intention tremor, the quietness of *c*) normal *resting* is disturbed by chorea or athetosis Each of these seems to be a condition where the interruption of some neural mechanism "releases" an underlying rhythmic mechanism from a control that is usually superimposed over it.

There is reason to believe that such rhythms are, in general, a fundamental pattern of response of a control system (Wilson, 1967) If a given system does not show such a rhythm or oscillation, it means that some component has been added so as to achieve a smoothing of the response One should recall that the usual condition of a simple system with a negative feedback is one of oscillation (see Grodins, 1963, p 96 ff) As the output increases and the feedback becomes stronger, the feedback is returned as a negative input that lessens the output, with the result that the feedback likewise becomes less intense This permits the cycle to start again and an oscillation follows If the oscillation is not in turn controlled or "damped," and if time relations are what is called "tuned," the oscillation may become progressively greater so as to destroy the system One way of preventing such oscillation is to detune it in some way, or to introduce secondary feedback loops having time constants different from the first one Another way is to add feedbacks having detectors that signal, not where the system is, but where it is going, or how fast it is changing in a given direction Neural circuits having these properties seem to be responsible for smoothness and stability of movement in the somatic motor system, and these concepts seem to offer a useful hypothesis for thinking about involuntary movements If the concepts are correct, one can see that although it might be possible to remove a focus from which an unwanted movement such as chorea or athetosis originates, contrariwise a tremor of resting posture (in parkinsonism) or of voluntary movement (intention tremor) can be relieved only by altering the phase relationships of the system, or actually interrupting the feedback Or, as noted earlier, the magnitude of the oscillation, but not the oscillation per se, may be reduced by decreasing the power applied to the system

Rhythms may originate at any level of the nervous system For example, a single detector creates a rhythmic pattern of nerve impulses, as does a motor neuron, the most fundamental of all repetitive activity Its frequency depends upon intensity of stimulation, sensitivity of the detector or the postsynaptic membrane, and duration of the refractory period This phenomenon has been designated as "a rhythmic response to a steady state" (D H Barron, personal communication) It is responsible for signal generation, as described in chapter 1. If it occurs in the central nervous system it may account for what appears to be "spontaneous" activity including some voluntary movements

When circuits or loops of neurons function together, the possibility of another type of rhythm is introduced, a second order type in which bursts of nerve impulses acquire a pat-

tern that is a frequency modulation of the original train It is this second order of rhythm that underlies the involuntary movements just considered, as well as the electroencephalogram (see next chapter) and rhythmic activity in other levels of the neuroaxis, as follows

1) On a purely reflex basis there is the phenomenon of clonus (p 9-97), the repetitive contraction of a muscle after its tendon is stretched (Fig 9 88) It appears especially in extensor muscles of decerebrate preparations when the myotatic reflexes are hyperactive (Creed et al , 1932)

2) More highly organized is the rhythmic stepping that Sherrington (1906) and many other authors have studied in spinal animals Sherrington found that it did not depend upon innervation from muscles involved, nor upon any other one type of sensory stimulation, and so concluded that it originates in the spinal cord It is presumed to be brought about by nerve nets that are self-exciting in a fashion that alternately stimulates and inhibits both flexors and extensors in a reciprocal fashion in both hind limbs

3) From the brainstem there arise the rhythmic trains of impulses that maintain pulmonary ventilation, as well as another form of rhythm that sometimes appears in blood pressure records as Traube-Hering waves (sect 3, chap 9)

4) Rhythms of feeding and drinking, as well as those associated with temperature regulation and with certain phenomena of reproduction such as the estral and menstrual cycles come from the hypothalamus and pituitary gland

5) The levels of basal ganglia and cerebellum are represented both by the presence and absence of movements described in this chapter

6) Finally, many of the voluntary movements that are believed to begin in the motor cortex are rhythmic in nature, including writing, typing, dancing, and a multitude of others

In certain of these examples it is possible to identify the negative feedback pathway that maintains the oscillation For clonus it is muscle spindles stretched when the muscle

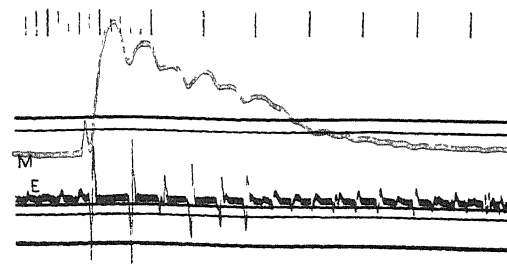

Fig 9 88 Clonus in lightly stretched quadriceps muscle of decerebrate preparation Clonus was induced by tapping the tendon of the muscle Rhythmicity is shown both in mechanical record (*upper*) and electromyogram (*lower*) (Creed et al 1932)

relaxes and the limb moves passively In a cat with a low decerebration the rhythm of pulmonary ventilation may be created by stretch receptors in the lungs that serve to limit each inspiratory excursion If the decerebration is still lower, however, and the vagal nerves are both cut, another variety of rhythm may be seen that is analogous to the stepping of Sherrington's spinal dog after the afferent nerves had been cut This type of rhythm comes from circuits, from negative feedbacks, that are within the nervous system and do not require a peripheral detector They may or may not include a pacemaker, a master neuron that always fires first But they must include connections such that activity eventually is fed back as inhibition that suppresses the original output

The tremor at rest of a patient with lesions of the basal ganglia, therefore, indicates that postural mechanisms are normally rhythmic when cortex, cerebellum, brainstem, and spinal cord are intact and when voluntary motion is not in progress It is the function of substantia nigra and globus pallidus to mask this rhythmicity so as to maintain a stability of posture Similarly, the movements that originate in motor cortex on a "voluntary" basis show an obvious and disturbing rhythm unless they are smoothed out by the circuit that includes the cerebellar cortex What is known about the organization of this part of the brain is consistent with the interpretation that a phase shift is introduced by the more circuitous pathway from cortex to pons to cerebellum and back to thalamus and cortex

Organization and Activity of the Cerebral Cortex

The human cerebral cortex (or *pallium*) has a total area of about 2,200 cm ^{2}, not more than a third of this lies upon the free surface or crown of the convolutions The remaining two-thirds of the gray mantle of the cerebrum occupies the walls and depth of the sulci The total number of nerve cells in the human cerebral cortex has been estimated at around 14×10^9 The number of fibers received from and projected to lower levels of the nervous system is in the neighborhood of 200 million Added to these are fibers, many times more, which connect cells within the cortex (association fibers) Because many of these fibers are not myelinated, their courses are not easily traced from one region to another Of those that are myelinated, a prominent number join the cortices of the two sides via the corpus callosum ("hardened body") that is a major portion of the white matter in the center of each hemisphere

FINE STRUCTURE OF THE CORTEX

When the grey mantle of the cortex is cut transversely, the fine structure is seen to be organized in layers or laminae (Fig 9 89) These layers do not show identical histological appearances throughout the extent of the cortex characteristic differences in the depth of the individual layers and their cellular components are found in the various regions The six layers from the surface inwards are shown in Figure 9 89, as they were named by von Economo they include the following

I Molecular (or plexiform) *layer,*
II External granular layer,
III Pyramidal cell layer,
IV Internal granular layer,
V Ganglionic layer (internal pyramidal layer)
VI Fusiform cell layer

It should be emphasized, however, that even the number of layers is not a feature common to the entire cortex In man one-twelfth of the cortical area shows fewer than six layers (typically three), this portion, the *allocortex* or *archipallium*, comprises the cortex of the olfactory lobe and limbic system (chap 8, p 9 156), and includes the pyriform area and the hippocampal, supracallosal, cingulate, and olfactory gyri The six-layered cortex, which in man constitutes the remaining eleven-twelfths, but which in lower mammals is a much smaller fraction of the whole, is called the *isocortex* or *neopallium*

The greater part of the human laminated cortex shows the cytoarchitectural features described above, and is therefore sometimes referred to as the *homotypical* cortex In other more restricted areas the cortex departs from the typical cytological appearance, chiefly in the preponderances of the small granular cells or of the pyramidal elements, and is called *heterotypical* In areas in which the internal granular layer is absent or practically so, and in which pyramidal cells predominate, the cortex is called *agranular*, it tends to be thick because of the presence of the larger types of neurons When the small, granule-like cells form a prominent internal granular layer with few pyramidal cells, it is called the *granular* cortex, this type is particularly thin at the frontal and occipital poles of the hemispheres

LOCALIZATION OF FUNCTION IN THE CEREBRAL CORTEX

Many authors have tried to make some significant correlation between fine structure and function of the several cortical areas These attempts have not been particularly helpful, except in two instances One is in the case of the cortex of the precentral region (areas 4 and 6), which is of the agranular type The granular layers (II and IV) are shallow, being encroached upon by the expansion of the pyramidal layers III and V In the deep part of layer V of area 4 (the area gigantopyramidalis) are situated the characteristic giant cells of Betz

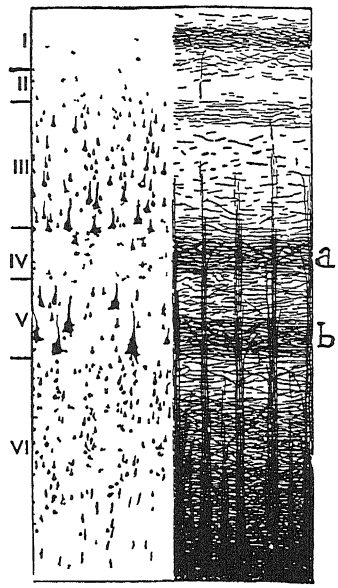

Fig 9 89 Microscopic appearance of cerebral cortex (area 4) as stained for neurons (*left*) and for fibers (*right*) Layers are identified with large cells of Betz in layer V Outer and inner bands of Baillarger are indicated as *a* and *b*

(60 to 80 μm, in their greatest diameters) (see below) These cells contribute fibers to the corticospinal tracts In area 6 rostral to area 4 the granular layers are also inconspicuous even though the large cells of Betz are absent

In the cortex of the walls of, and surrounding the calcarine fissure—the *area striata* or *visual area*—the outer and inner granular layers (II and IV) are expanded at the expense of the pyramidal layers (III and V) This very finely granular type of cortex, also called from its "dusty" appearance under the microscope the *koniocortex*, is characteristic of sensory areas It is present, though to a less fully specialized degree than in the visual cortex, in the postcentral gyrus (somesthetic area) and in Heschl's gyrus (auditory cortex)

Campbell (1905) mapped the cortex into 20 areas which can be differentiated on the basis of their cytoarchitectural characters This number was raised to 47 by Brodmann (1909), and further subdivided by Vogt and Vogt (1919) to make a total of 200 Bailey and von Bonin (1951), however, in a careful reappraisal of the matter concluded that the only significant subdivisions are the following

a) *Allocortex* of the hippocampal region and the pyriform lobe,

b) *Agranular cortex* of the precentral region and the anterior limbic area,

c) *Koniocortex* of the primary sensory areas (the somesthetic areas of the postcentral gyrus, the visual cortex of the calcarine area, and the auditory cortex of Heschl's convolution on the superior surface of the first temporal gyrus),

d) *Eulaminate cortex* of most of the remainder of the mantle of the cerebral hemisphere

Differences, most of them minor, within this broad outline are demonstrable For example, the agranular cortex of the anterior limbic area partakes of some of the characteristics of the allocortex (see chap 8, p 9-156) The koniocortex of the visual area is more complex than that of the somesthetic and auditory areas, and there are minor variations in different parts of the eulaminate cortex which are not of significance here In the following discussion, therefore, the numbers assigned to cortical areas by Brodmann will be used merely for convenience in identifying cortical loci (Fig 9 90) The principal gross anatomical subdivisions of the cerebrum are shown in Figures 9 91 and 9 92

ELECTRICAL ACTIVITY OF THE CORTEX

Electrical activity in the nervous system is of two types, evoked or spontaneous *Evoked* activity is elicited by applying an appropriate stimulus to a sense organ or to the nervous system itself and recording the resultant electrical activity with either a gross electrode or a microelectrode (Landau, 1967) Examples of such activity are shown in Figure 9 93 *Spon-*

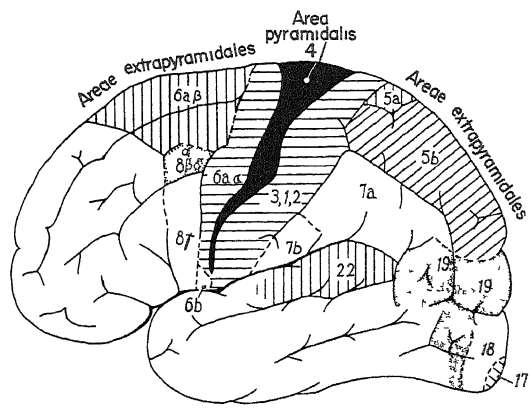

Fig 9 90 Lateral view of the human cerebral hemisphere showing the numbers assigned to the several areas After Brodmann and the Vogts from Ranson and Clark, 1959

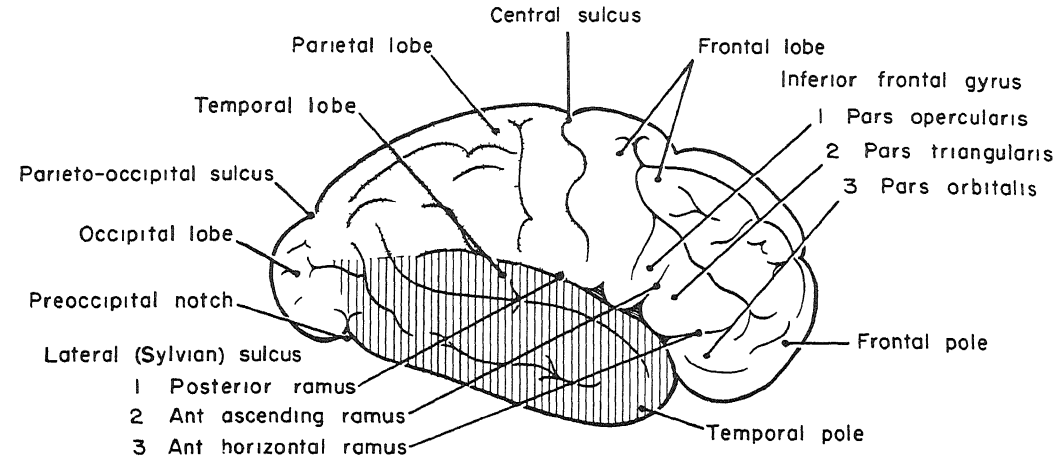

Fig 9 91 Major landmarks of lateral surface of cerebrum Lobes are indicated by shading (temporal) stippling (parietal) or their absence (occipital frontal) From Truex and Carpenter 1969

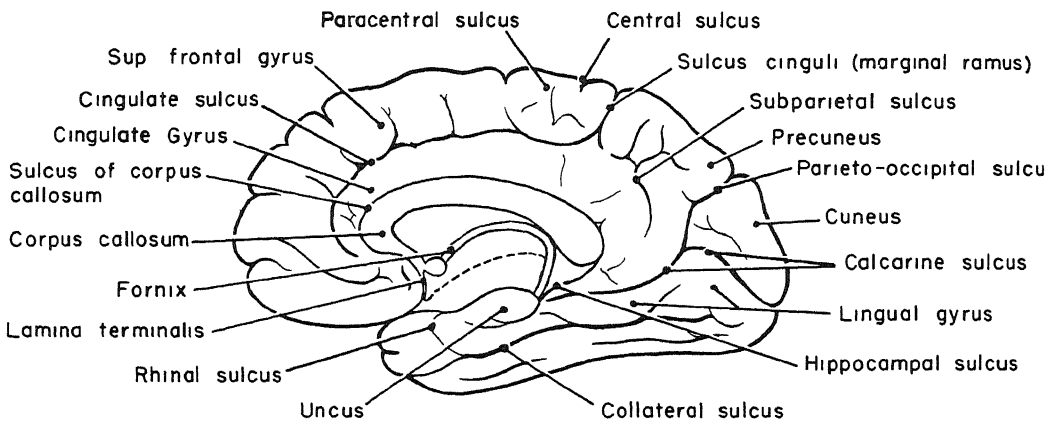

Fig 9 92 Major landmarks of the medial surface of the cerebrum with brainstem cut across and removed below the level of the diencephalon (Truex and Carpenter 1969)

taneous electrical activity is present although the animal is not being stimulated. An example of spontaneous activity is the electroencephalogram, which will be described in more detail later Examples of spontaneous activity are also shown in Figure 9 93 Evoked and spontaneous activity have been subdivided according to whether the activity represents the "spikelike" action potential of the neuron recorded with a microelectrode or a sum of the longer lasting postsynaptic potentials described in chapter 4

The action potential of a neuron in the central nervous system may be recorded either by extracellular or by intracellular techniques For the latter purpose fine electrodes can penetrate a single cell without producing any apparent damage and can record not only the action potential but also the resting potential Both extracellular and intracellular electrodes can record postsynaptic potentials With an intracellular electrode the postsynaptic potentials are derived from the cell penetrated With an extracellular electrode, be it a microelectrode or a larger one, the postsynaptic potentials recorded are considered to be largely composed of the sum of the potential changes of many cells It is this summation that yields the electroencephalogram (Morrell, 1967), and also the slow wave evoked reponses recorded from the nervous system in response to artificial stimulation

The Electroencephalogram (EEG). In 1875 Caton first discovered that an electrode placed on the cortex of experimental animals would record spontaneous fluctuations of electrical

activity Although this discovery was widely reported at the time, the EEG did not receive significant attention for over 50 years In 1929, Berger reported that changes in electrical potential could be recorded from the head of the human subject by means of electrodes applied to the scalp or needle electrodes placed in contact with the periosteum of the skull These brain potentials were later studied by Adrian and Matthews (1934) In normal subjects the EEG may be characterized by three frequency bands, the α, β, and Δ rhythms (A faster rhythm (γ) appears in rare instances) The α rhythm consists of rhythmical oscillations in electrical potential occurring at the rate of 8 to 10/sec The waves have a voltage of about 50 μV on the average The β rhythm has a frequency of 15 to 60/sec and the waves are of lower voltage (5 to 10 μV), the frequency of the Δ waves is from 1 to 5/sec and the voltage is relatively high (20 to 200 μV) No precise cytoarchitectural area can be said to have a characteristic rhythm as was once supposed, but differences are found between rather large areas of the cortex Thus, the α rhythm dominates records from the occipital region or from the posterior parts of the parietal and temporal lobes The sensorimotor region emits waves with a frequency of from 20 to 25/sec, the anterior frontal areas give out waves at the rate of from 8 to 5/sec

The α rhythm occurs in the *inattentive* brain, as in drowsiness or light sleep, narcosis or when the eyes are closed, it is abolished by visual and other types of stimulus or by mental effort (e g , mathematical calculation) The Δ waves can be recorded very rarely from a normal adult while awake, but appear normally during deep sleep or during the waking hours in early childhood Generally speaking, their presence in an adult, except during sleep, indicates some pathological process in the brain—tumor, epilepsy, raised intracranial pressure, mental deficiency, or depression of consciousness by toxic or other factors When present they tend to displace the α rhythm Neither the β nor the Δ waves is affected by opening or closing the eyes

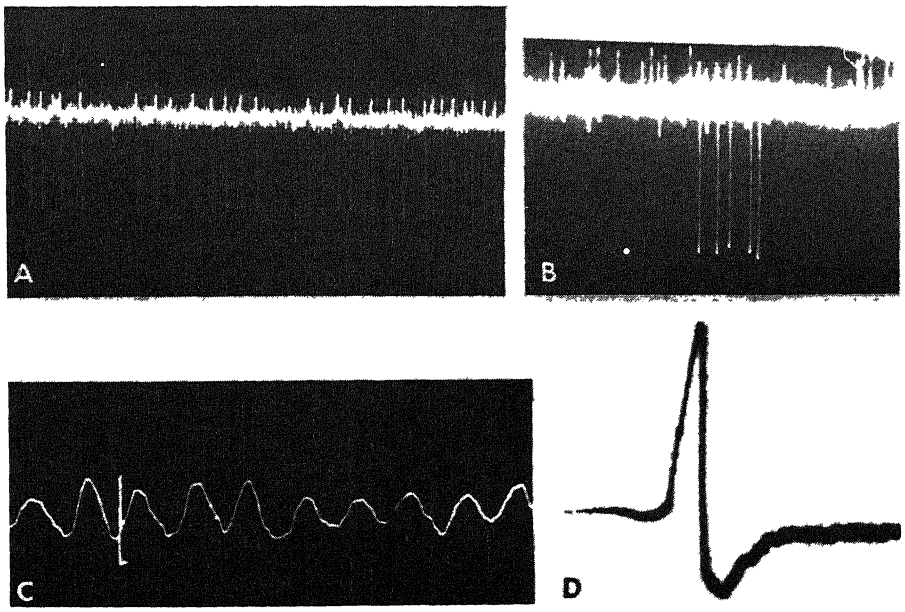

Fig 9 93 Examples of spontaneous and evoked cortical activity *A* spontaneous single unit action potentials recorded from cerebellar cortex with a microelectrode The 'spikes represent the action potentials of a single neuron *B* Evoked single unit action potentials recorded from primary auditory cortex with a microelectrode The auditory stimulus (a click) was presented at the point in time represented by the dot The time delay between stimulus presentation and response represents the latency of the cortical response *C* Spontaneous slow wave activity recorded from the surface of the scalp with a gross electrode (the electroencephalogram) The subject was awake and relaxed with eyes closed The waves have a frequency of about 10/sec—the α rhythm *D*, Evoked slow wave activity recorded from the surface of the primary auditory cortex with a gross electrode The auditory stimulus was applied at the start of the trace

The EEG is affected profoundly by certain general states *Hypoxia* causes at first a moderate slowing of the rhythm, but as the oxygen lack becomes more severe large Δ waves appear, with persistent and severe hypoxia the amplitude of the waves declines and may reach almost the vanishing point *Hypoglycemia* causes an effect somewhat similar to that of hypoxia, when the blood sugar falls below about 40 mg %, Δ waves (1 to 3/sec) are seen, though the α rhythm is not abolished entirely The effects of hypoxia and hypoglycemia enhance one another, their summed effects being much greater than the effect of each alone Hyperglycemia has little effect upon the cortical potentials Increase in carbon dioxide tension increases the rate, but reduces the amplitude of the waves Blowing off of CO_2, as by overbreathing, has the opposite effect

Abnormalities of the electroencephalogram in brain tumor, especially of so-called silent areas of the brain, and in epilepsy, may be of diagnostic value

However, the electroencephalogram may give misleading information as to the location of a brain tumor and a "normal" electroencephalogram in the presence of a brain tumor is not rare Epileptic seizures (see Chap 9) are characterized by pronounced departures from the normal rhythm In *petit mal* attacks, large slow waves appear about a second before the attack is clinically manifest, and displace the previous rhythm Each large wave is followed by a sharp spike deflection (Fig 9 94) In the tonic stage of a *grand mal* seizure, waves of relatively high frequency (10 to 30/sec) and of low voltage appear, but as the attack progresses into the clonic phase these fast waves give place to slower and large waves which continue into the stage of stupor following the seizure Δ waves may be a prominent feature of the electroencephalogram of epileptics between seizures Approximately one-third of epileptic adults have "normal" electroencephalograms

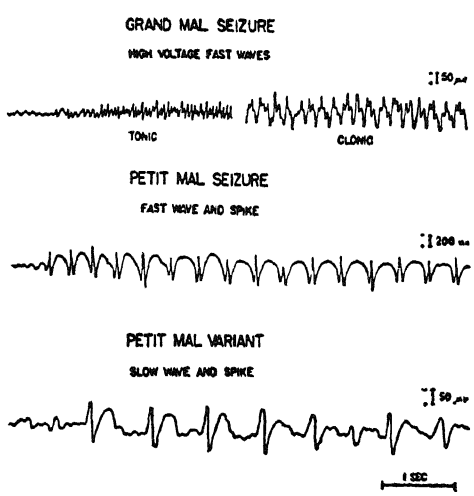

Fig 9 94 Electroencephalograms as recorded during three different types of epileptic seizure

THALAMOCORTICAL PROJECTIONS

Thalamic pathways to the cortex may be placed in two categories the specific and the nonspecific systems (Fig 9 95) Projection fibers of the *specific* system originate in the sensory relay nuclei (e g , the geniculates and the ventral posterior nuclear group) and the association nuclei (e g , pulvinar, lateral nucleus) and, in general, project directly to the cortex Typically these fibers show relatively little lateral spread in the cortex This is particularly true of fibers originating in the relay nuclei Consequently, electrical stimulation of restricted regions in these specific thalamic nuclei results in a relatively discretely localized cortical evoked potential This evoked potential has a latency of 1 to 5 msec If a specific thalamic nucleus is stimulated repetitively at a rate between 6 and 12 pulses/sec , cortical evoked responses to successive pulses may become larger These are called *augmenting* responses and they are limited to the specific sensory cortex

The *nonspecific* thalamic nuclei such as the intralaminar group and nucleus reticularis give rise to a projection system considered to be the rostral portion of the ascending reticular activating system This nonspecific thalamic system is widely distributed over the surface of the cortex, including those cortical areas to which the specific relay nuclei project Many of these nonspecific thalamic nuclei have not been shown to have any direct pathway to the cortex, the conclusion being that these nuclei send fibers to the cortex by an indirect, multisynaptic pathway The exact nature of this indirect pathway remains to be clarified

The specific and nonspecific systems are not independent, but interact with each other at all levels between the brainstem and cortex Many physiological and anatomical studies have shown that collateral fibers from the

somatic, visual, and auditory specific sensory systems enter the diffuse system in the brainstem and thalamus Conversely, fibers pass from the centrum medianum, a nonspecific thalamic nucleus, to terminate in specific thalamic relay nuclei (Nauta and Whitlock, 1954) Electrophysiological studies have shown that stimulation or extirpation of regions of either the specific or nonspecific systems will influence the responses of the other system For example, recruiting responses recorded from primary visual cortex are increased in amplitude after destruction of the lateral geniculate (Hanberry and Jasper, 1953) This increase in the recruiting response recorded at primary sensory cortex has also been seen after destruction of the other major thalamic sensory relay nuclei Moreover, the responsiveness of sensory cortex to specific afferent stimulation is modified by the activity of the nonspecific projections (Fig 9 95) A possible interpretation of these and many other related studies is that the activity of the nonspecific system controls the excitability of the cortex

Fig 9 95 Thalamo-cortical projections The labels show region of origin of diencephalic fibers projecting to cerebral cortex From E Walker as summarized by Penfield and Jasper 1954

Regions with Sensory Functions

How the cerebral cortex, thalamus, and other levels of the central nervous system transmit impulses that lead to sensation is fully considered in section 8 of this textbook Consequently, only a brief account is needed here (Fig 9 96)

SOMESTHETIC AREA OF THE PARIETAL LOBE

The *postcentral gyrus*, i e , the band of cortex lying behind and including the posterior lip and wall of the fissure of Rolando (areas 3, 1, and 2) is sensory in function and is known as the *somesthetic area* This band of sensory cortex turns over the upper border of the hemisphere, and extends down the mesial surface as far as the cingulate gyrus As in the case of the primary motor area, (see later), the sensory areas of the body are, in a general way, represented mainly in inverted order, from the lowest part of the mesial surface to a corresponding part of the lateral surface (see Fig 9 97) The order of this cortical representation conforms closely to that of the dermatomes, i e , to the spinal innervation For example, the cortical sequence for the upper limb (monkey) is postaxial arm, occiput, ear, side of head, neck, shoulder (C2–C6), preaxial arm, forearm, wrist, hand, digits (C7, C8, T1) This dermatomal representation, however, is not in continuous numerical sequence from head to tail For example, if the sensory band of cortex (which turns over the upper border of the hemisphere) could be straightened out, it would appear quite clearly that the projection of the dermatomes from the upper thorax to the tail (thoracic 1 to caudal 4) is in an order the inverse of that of the spinal segments, whereas the representations of the head and neck are not inverted, the cervical segments being represented in ascending numerical order from above down, with the ophthalmic division of the fifth nerve following C8 (Fig 9 97) There is no obvious explanation for this arrangement Excisions of portions of the somesthetic cortex are followed by disturbances of cutaneous and kinesthetic sensations in the corresponding region of the opposite side of the body These subside to a greater or lesser degree with the passage of time

Cushing (1909), and later, Penfield and his associates (see 1950, 1966) stimulated different parts of the somesthetic areas in conscious patients, sensations on the contralateral half of the body were experienced, their locations bearing a constant relationship to the point stimulated.

The sensory area of the cortex is not confined to the postcentral gyrus, but extends forward into the precentral gyrus Penfield and his associates found that 25% of stimulations of the latter area in patients caused a sensation, with or without a motor response On the

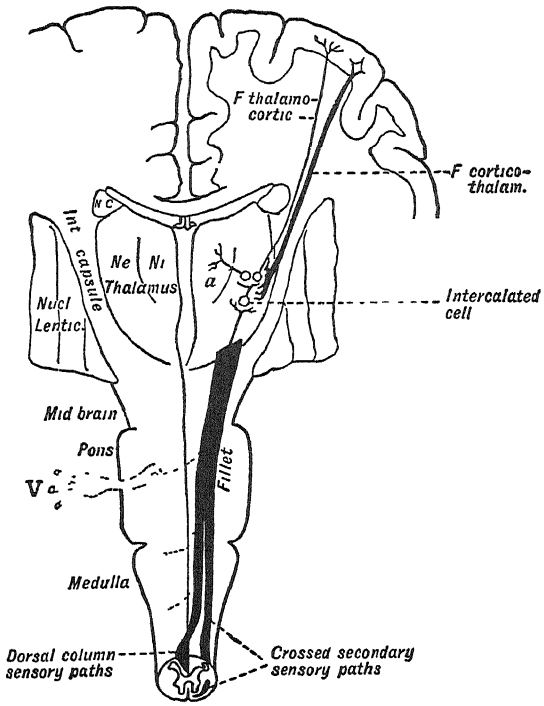

Fig 9 96 Outline of pathways by which sensory impulses ascend from spinal cord through brainstem to thalamus and thence to somesthetic areas of parietal cortex

other hand, 20% of stimulations of the postcentral gyrus gave a motor response, instead of or accompanied by a sensation Moreover, ablations of postcentral areas cause motor defects which are not due simply to loss of kinesthetic sense It appears that the precentral and postcentral areas are knit together by connecting neurons, and are so interrelated functionally as to be called appropriately, taken as a whole, the *sensorimotor area*

The extent of the sensory representation in the postcentral gyrus is a function of the number of sensory fibers reaching the cortex from a given region It is greatest for those parts of the body which are of most importance in acquiring information concerning surrounding objects Thus, in man and in the monkey the cortical area for the hand and arm is larger than that for the trunk or leg A large facial representation in man is in keeping with the generous sensory innervation provided to the face by the three divisions of the trigeminal nerve

Somatic sensation as well as the visual and auditory senses have a double representation in the cortex of each hemisphere This dual somatic representation was first observed by Adrian (1940), in the case of the claws of the cat The somesthetic area described above and long recognized, is now called the "primary" sensory area, or, as Woolsey (1958) has suggested, *somatic area I* The more recently discovered sensory area is called *somatic area II* Corresponding terms for the dual visual and auditory areas are employed, namely auditory and visual areas I and II Somatic area II lies in the upper wall of the Sylvian fissure, that is, below the face area of somatic area I, which is much larger in extent The order of representation in sensory area II is the inverse of that in sensory area I, the face being above the arm in the upper part of the wall of the fissure with the foot at the bottom The significance of the dual cortical representation is unknown

THE TEMPORAL LOBE

The primary cortical center for hearing is situated in the transverse gyrus of Heschl lying in the floor of the lateral cerebral (Sylvian) fissure, and an adjoining small area of the superior temporal gyrus Fibers from the medial geniculate body reach this *auditosensory* area (area 41) via the posterior limb of the internal

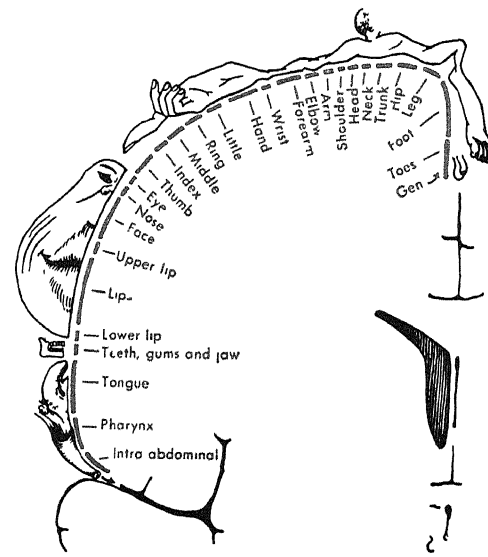

Fig 9 97 Sensory homunculus Diagram illustrates the region of the body from which sensory fibers enter the cortex at each location (Penfield and Rasmussen, 1950)

capsule, they constitute the *auditory radiation* In the auditosensory area the fundamental auditory sensations—intensity, and pitch—are appreciated The area is bilaterally represented Equilibratory sense is represented in the posterior part of the first temporal convolution Stimulation of this region in conscious patients causes dizziness or nausea, a sense of swaying, falling, or of rotation

THE OCCIPITAL LOBE

The gray matter forming the walls of, and surrounding the calcarine fissure (on the medial aspect of the occipital lobe) constitutes the primary cortical center for vision—the *visuosensory area* From the broad stripe of Gennari which can be seen with the naked eye this area is commonly known as the *area striata* or, following the numerical terminology, as area 17 It is considered in more detail in section 8 Its histological features have already been touched upon

The *second visual area* wherein the visual sensations are interpreted and integrated into more complex perceptions is contiguous to the area striata and lies on the lateral aspect of the occipital lobe (area 18)

Stimulation of the anterior part of the lateral surface of the occipital lobe causes conjugate deviation of the eyes to the opposite side (occipital motor eye field, area 19) In man, visual hallucinations, such as, flashes of light of different colors, or definite images have been evoked by the electrical stimulation of area 18 or 19

SENSORY FUNCTIONS OF ASSOCIATION CORTEX

Sensory stimuli produce evoked responses at a number of cortical regions other than primary sensory cortex These regions have been described in the cat as the anterior part of the sigmoid gyrus and the suprasylvian gyrus (Albe-Fessard and Rougeul, 1958). In the monkey, the corresponding areas have been described as superior temporal cortex, superior frontal cortex and parietal association cortex (area 5) (Albe-Fessard et al , 1959) These responses are particularly evident in the unanaesthetized animal or in animals anaesthetized with chloralose They are more labile than primary sensory responses, showing wide variations in magnitude of response to repetitions of the same stimulus When stimuli are repeated, responses in association cortex will fail to appear at every stimulus if the repetition rate is higher than approximately 5/sec On occasion several seconds or minutes may be required for full recovery of response amplitude

One of the outstanding characteristics of association cortex is the diversity of stimuli that converge on these areas For example, a single cortical electrode may record responses from stimulation of many different regions of the surface of the body Localization seems to be poor in contrast to the relatively high degree of specificity seen in primary sensory cortex Stimulation of a variety of sensory modalities will also produce responses at one region Auditory, somatic, and visual stimuli may produce evoked responses from a single electrode location In addition to this overlapping of fields in association cortex, there is also interaction of these sensory modalities (Berman, 1961) Studies of the responses of single neurons with microelectrodes (Amassian, 1954) have shown that a single unit in association cortex will respond to stimulation of any of the limbs or to stimulation of other modalities

Electrophysiological study of the pathways by which sensory impulses reach association cortex have shown that responses remain after ablation of the relevant primary cortical sensory areas (Albe-Fessard and Rougeul, 1958) and after extensive destruction of the mesencephalic reticular formation (Buser et al , 1959) Coagulation of the centrum medianum of the thalamus, however, will abolish the sensory evoked responses in the association cortex ipsilateral to the lesion (Albe-Fessard and Rougeul, 1958) Electrical stimulation of the centrum medianum will also elicit short latency responses in those regions defined above as association cortex On the basis of such evidence, Albe-Fessard concluded that the sensory input to these cortical areas arrives largely via the centrum medianum

Experiments in which chronically implanted electrodes were used to record evoked responses in association cortex in unanaesthetized, behaving cats have shown a number of relationships between amplitude of evoked response and various behavioral activity

(Thompson and Shaw, 1965) Response amplitudes recorded at suprasylvian gyrus as a result of visual, auditory and somatic stimuli (light flash, click, and forepaw shock) are decreased when the animal is active, relative to amplitudes in the resting state Novel stimuli in any of these modalities will reduce the magnitude of response evoked by stimulation in any of these modalities Response amplitude is also decreased when the animal orients toward a stimulus These results indicate that evoked responses in association areas are modified by activity in other parts of the central nervous system

Cortical Motor Mechanisms

PRECENTRAL CORTEX OF THE FRONTAL LOBE

Area 4 is a tapering strip of agranular cortex lying with its wider end at the upper border of the hemisphere, in front of the central fissure (Rolandic), and occupying the posterior part of the precentral convolution A good part of this area is buried, for it covers the anterior wall of the central fissure It also turns over the upper border of the hemisphere and extends down the mesial aspect as far as the cingulate sulcus Area 4 is a center for control of movement It gives origin to an important part of the corticospinal tracts, and also projects to the pons (frontopontine tract), corpus striatum, red nucleus, thalamus, and the subthalamus Area 4 and area 6 just ahead of it are connected by intracortical fibers The muscles of the various parts of the body are represented in area 4 on the mesial and the lateral surfaces, in an order similar to sensory representation in the postcentral gyrus It is, in general, the inverse of that in the body itself, namely, toes, ankle, knee, hip, trunk, shoulder, arm, elbow, wrist, hand, fingers, brow, eyes, face, larynx, jaw, and tongue (Fig 9 98) The parts of the face are not inverted By suitable electrical stimulation of different parts of this area, movements of muscles on the opposite side of the body can be evoked

The careful studies of Woolsey (1958) on the monkey suggest that the distal parts of the extremities, i e , the hands and feet, are represented near the central fissure while the more proximal joints, i e , shoulders and hips, and the trunk, are represented somewhat more

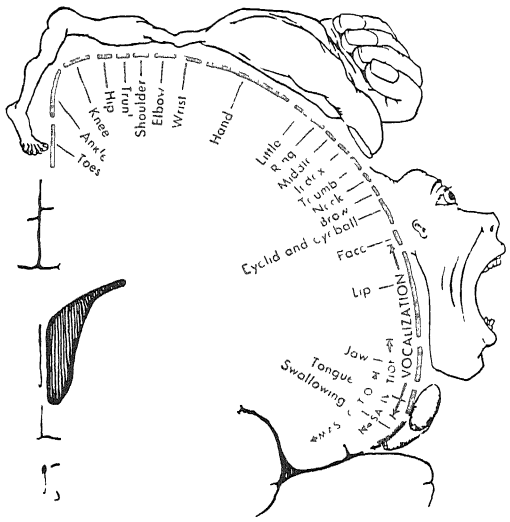

Fig 9 98 Motor homunculus Region of origin of cortical control of parts of the body as determined by electrical stimulation (Penfield and Rasmussen 1950)

anteriorly With suitably controlled stimuli discrete movements limited to a small part of the extremity or even to a single muscle may be elicited Although most of the control of the precentral cortex over the muscular activities of the body is exerted contralaterally, there is also some control over muscles on the same side of the body This ipsilateral innervation is greater in the proximal joints of the extremities than in the distal parts and is greater in the lower than in the upper extremity Furthermore, this ipsilateral innervation by the precentral motor cortex is greater in monkeys than in man

A study by Chang et al (1947), who recorded movements of single muscles, indicates that individual muscles can be stimulated at the cortical level There are, however, certain curiosities about the movements induced by such stimulation Chang and his associates succeeded in recording contractions of single muscles in a reproducible fashion because they strictly controlled both the condition of their anesthetized animals and the circumstances of the stimulation If stimuli are applied more casually to the motor cortex, one finds less constant results For instance, the nature of the motor response obtained from a given electrode placement may change if the frequency or strength of the stimulation is altered Second, the response often depends upon the initial position of the limb, if a limb is passively flexed, stimulation may give extension,

whereas if it is previously extended the same stimulation may yield flexion Third, if the site of stimulation is gradually moved along the gyrus, the response has a tendency to "follow" the movement of the electrode, so that eventually a contraction of arm muscles, for example, may be obtained from what is ordinarily the motor area for leg This shows that there is a difference between motor representation in the grey substance of the spinal cord, on the one hand, and in the cerebral cortex Spinal motor neurons are invariently connected to a given muscle, cortical neurons, on the other hand, seem to connect with various pathways, the nature of the connection depending upon many different factors It is only when all such factors are maintained constant that completely uniform results can be obtained from stimulation of the motor cortex, especially in laboratory primates and in human subjects Granit (1970) has called the population of motor cells that can evoke contraction of a given muscle a "colony"

A *supplementary motor area* (Fig 9 99) on the medial surface of the hemisphere in both man and monkey lies anterior and ventral to the primary motor area described above (Penfield and Welch, 1951, Woolsey, 1958) In it the entire body is again represented The head and upper extremity are represented farther forward and closer to the edge of the hemisphere while the lower extremity is represented more posteriorly and nearer to the corpus callosum The threshold of this supplementary motor area is somewhat higher than that of the primary motor area 4 The function of this supplementary area has not yet been well defined

The *corticospinal fibers* arise from the precentral gyrus (area 4 in the monkey) but not from area 6 (Verhaart and Kennard, 1940) Yet both of these areas do give rise to fibers which descend directly or indirectly to subcortical centers (e g , basal ganglia, thalamus, reticular formation, pontine nuclei, etc) This means that the ablation of areas 4 or 6 is not the same as section of the cerebral peduncle or the medullary pyramid, neither will a cortical lesion give rise to a clinical picture typical of destruction of the motor pathways through the basal ganglia, etc

Neural Deficits Following Cortical Lesions. *Cat or Dog.* Destructive lesions of the various parts of the precentral motor cortex

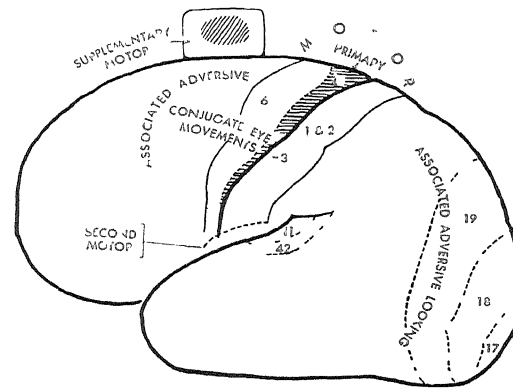

Fig 9 99 Human motor cortex Primary motor area (*4*) is surrounded by areas that are also electrically excitable Supplementary area is on medial surface of hemisphere (Penfield and Rasmussen 1950)

have certain important characteristics If one bilaterally removes the excitable motor cortex (the sigmoid gyrus) from both hemispheres of a dog or cat, or even if all the cerebral cortex is removed, the animal is not completely paralyzed It can sit, stand, walk, or run almost normally, as noted in the preceding chapter The deficits it shows are in the more stereotyped reactions that have been called *placing* and *hopping reactions* These deficits have been analyzed by Bard and Brooks (1934) as follows

Placing Reactions *1*) If a cat is held in midair with legs dependent and chin held up so that it cannot see anything below or in front, contact of the backs of the forepaws with the edge of the table is followed by a quick movement of the limbs which brings the paws, pads down, precisely upon the surface of the table *2*) If the forelimbs of a cat are held down while the chin is brought in contact with the table near its edge, the forepaws when released are instantly raised and placed upon the table beside the chin This movement is usually followed by extension of the limbs and the assumption of a standing position *3*) If the fore or hind limbs of a cat standing or sitting upon a table are pushed over the table's edge, they are immediately lifted and placed in their original positions *4*) If one abducts, without holding, the limb of a standing cat, it is instantly returned to its previous position *5*) If a blindfolded cat is suspended in the air with forelimbs free, and its head brought toward some obstacle, at the instant that the vibrissae come into contact with the object the forepaws

are raised and accurately planted upon the surface of the object The first three of these reactions are due to stimulation of receptors upon the body surface (exteroceptors) and probably also of proprioceptors in muscles and tendons The fourth is a purely proprioceptive reflex, the last is initiated from tactile receptors

Hopping Reactions They involve limb movements that serve to maintain the standing position against any force acting upon it in a horizontal plane When, for example, a cat held so that its body is supported upon one fore or hind limb is then pushed in one or other direction, the supporting limb hops quickly in the direction of the displacement, the foot being kept directly under the corresponding shoulder or hip The hopping reactions are probably dependent upon myotatic (stretch) reflexes

The placing and hopping reactions are controlled from the sensorimotor areas of the cerebral cortex Bard and Brooks found that removal of these regions from both cerebral hemispheres abolishes the placing reactions, and produces an extreme degree of deficiency in the hopping reactions Decortication (complete removal of the neocortex) produces no greater deficiency The control exerted by the cerebral cortex is entirely contralateral, i e , the component movements of the reactions on one side of the body are governed solely by the opposite side of the brain

Cortical Lesions in Monkeys or Man. If the precentral motor cortex is removed from both hemispheres of a monkey, the neural deficit is more severe than in a cat But over a period of months a considerable recovery is seen to the point that, although movements are stiff, visually controlled purposive movement can take place There is, however, permanent loss of what has been termed by Denny-Brown the "instinctive tactile grasping reaction" (1929) This reaction is described as an exploratory palpation which brings an object stimulating light touch into the palm or sole followed by "very facile" grasping Evidence from patients with lesions resulting from vascular accident, surgery, or head wounds indicates that although the ultimate deficit is clearly greater in man than in monkey, a certain amount of recovery of function is possible This recovery is believed to be due, in part, to a reorganization of remaining intact cortex Thus, in monkeys the subsequent removal of parietal (areas 3, 1, 2, 5, 7) or frontal (areas 9 to 12) cortex at some time after recovery from an earlier ablation of areas 4 and 6 increases the pre-existing motor deficit After recovery from localized lesions in hand area 4, hand movements can be evoked by stimulating an adjacent portion of area 4 which had not previously yielded hand movements (Glees and Cole, 1950) However, the ability of totally decorticate cats to move quite well within a short time after surgery indicates that there may be also a subcortical participation in recovery of function In general, the possibility of recovery of function decreases with age and a higher position on the phylogenetic scale Recovery is enhanced by good postoperative care, and training and time

Whereas in the cat and dog the *unilateral* removal of the motor cortex, or even the removal of all the cortex from one cerebral hemisphere, causes little motor disturbance, in the monkey there is an initial flaccid paralysis of the contralateral limbs Within a few days when the animal is again able to stand and run, the extremities contralateral to the hemidecortication are more awkward than the normal ones In jumping the animal may miss the bars of his cage occasionally with the involved digits, and often rests on the backs of the fingers or toes rather than on the palmar and volar surfaces as the normal animal does So long as his normal extremities are available he seldom uses the involved ones to pick up food, but he can do so in case of necessity This means that, although the contralateral extremities are not normal, they are far from being paralyzed Naturally one asks what is the source of the innervation of these extremities There can be little doubt that it is from the intact ipsilateral cerebral hemisphere, for if it is removed, the animal not only becomes paralyzed in the extremities contralateral to the new operation, but also in those affected by the original decortication as well In keeping with this interpretation is the evidence that ipsilateral movements, particularly in the lower extremity and particularly in the more proximal joints could be produced by electrical stimulation of the precentral motor cortex (Holmes, 1909, Bucy and Fulton, 1933)

In man the situation is similar but not identical If the precentral motor cortex is removed from one hemisphere the contralateral extrem-

ities are incapacitated but not completely paralyzed In some cases a slow and rather weak simultaneous flexion of all the digits of the hand can be produced voluntarily Movements at the shoulder and elbow and at the hip and knee are much fuller and stronger In the upper extremity the flexor movements tend to be better, whereas in the lower extremity extension at both the hip and knee is more extensive and stronger than flexion Movements such as these reflect the different functions of upper and lower extremities in man The arm and hand are primarily prehensile, designed to bring things to the individual or to pull him to them The leg, by contrast, is used for standing and walking, primarily as a supporting pillar The fact that the toes and foot cannot be moved is of relatively little importance to a patient who is able to move the extremity at the knee and hip, and so to walk in a very useful fashion, even though he limps and has to circumduct the involved foot with each step Evidence is not available to explain residual or recovered function after cortical injury in man, nevertheless, it seems likely that the ipsilateral cerebral hemisphere plays a role For instance, in a few human cases in which the upper part of the precentral motor cortex has been destroyed bilaterally by a tumor or by injury, both legs have been paralyzed If the movement in the lower extremities seen in hemiplegics were produced by the subcortical centers, then such a paraplegia would not be expected as the result of purely cortical lesions Furthermore, Bates has been able to produce ipsilateral movements by electrical stimulation of the medial surface of the cerebral hemisphere in man

Characteristics of Areas 4 and 6. As noted above, there are differences in function between the various parts of the precentral motor cortex Lesions of area 4 produce more severe and more specific deficits than do lesions of area 6 If area 4 is removed from the precentral motor cortex of monkeys bilaterally, leaving area 6 on one or both sides, the animal is still able to walk, sit, climb, and feed himself but the movements are limited and awkward and reside more about the proximal joints than in the digits (Bucy and Fulton, 1933) Similarly, if the medullary pyramids on the under surface of the medulla oblongata are sectioned in the monkey, the fine, delicate, precise movements of the digits are lost but crude awkward movements of the extremities, particularly those which are more stereotyped and which are related to standing, to progression, etc , are retained (Tower, 1940) Likewise, and somewhat surprisingly, destruction of the corticospinal fibers in the cerebral peduncle in man does not completely paralyze the contralateral extremities, nor is such an operation necessarily associated with the severely incapacitating hemiplegia of a destructive lesion in the motor cortex or in the internal capsule (Walker, 1952, Bucy, 1957) These patients are able to walk and to use their upper extremities for many useful purposes Although final decisive proof is lacking it seems probable that these voluntary movements present in the absence of the corticospinal fibers are produced over the multisynaptic system of the precentral motor cortex and the basal ganglia and other subcortical centers functioning together.

Another technique for studying the function of these regions is to remove all other parts of the precentral cortex and then to stimulate areas 4 or 6 in the absence of the other parts When this is done in a monkey the stimulation of either area 4 or 6 on a single side is capable of producing what appear to be useful movements in any of the four extremities This, again, verifies the ipsilateral as well as the contralateral nature of motor control It further demonstrates that this control may be exerted via the pyramidal i e , corticospinal, pathway from area 4, or via extrapyramidal, multisynaptic pathways from area 6

Only one reflex is clearly altered after destruction of the corticospinal tract from the precentral gyrus If the "foot" area in the uppermost part of area 4 on the medial surface of the hemisphere is destroyed or if the corticospinal fibers to the muscles of the great toe are divided a positive sign of Babinski, dorsiflexion of the great toe, can be elicited by stimulation of the skin of the sole of the foot The normal response to this stimulus is ventriflexion of the toe Destruction of other parts of the precentral region or section of other corticospinal fibers, of course, does not have such an effect

Irritative lesions involving area 4 give rise to localized clonic *convulsive seizures* The convulsive movement usually begins focally in some part of the body depending upon which part of area 4 is irritated There may be a localized twitching of the face, or of one or more

fingers, or of the foot or of the leg This convulsive movement may remain localized or it may spread to neighboring parts of the body or even become generalized This "march" of the convulsive involvement is typical of what is known as a jacksonian epileptic seizure and is dependent upon a spread of the excitation in the motor cortex This subject is discussed in chapter 9, p 9–181

The precentral motor cortex also appears to exert some control over various visceral and vascular activities, such as heart rate, vasomotor activities, gastrointestinal motility, perspiration Stimulation of the motor cortex may affect any of these phenomena under appropriate conditions These changes are said to be similar to visceral and other responses that accompany muscular exercise

Destruction of the precentral motor cortex (areas 4 and 6) results in a spastic hemiplegia, but this spasticity is less severe than that resulting from lesions at lower levels For example, the spasticity following lesions of the internal capsule is in general greater than that seen with cortical lesions In all probability this is due at least in part to some destruction in the basal ganglia, which is common with such lesions, as well as the destruction of the fibers descending from the precentral motor cortex The *pattern* of the increased tone, however, is similar with hemiplegias of both cortical and capsular origin, i e , the increase in tone in the upper extremity is in the flexor muscles With severe lesions at the mesencephalic level it is common to see spasticity even greater than is commonly seen with capsular or cortical lesions but the pattern in both the upper and lower extremities is an extensor one If the lesion is in the spinal cord, one may see either a paralysis with very severe extensor rigidity or a paraplegia in flexion, as has been discussed elsewhere

Grasping Movements and Tonic Innervation. Involvement of the anterior part of the precentral motor cortex, i e , of area 6, is not uncommonly associated with a group of phenomena to which various terms have been applied, e g , "forced grasping and groping," "grasp reflex," "tonic innervation," and so forth A description of these phenomena follows

1) Merely touching the skin between the finger and thumb with a pencil results in slow flexion of the fingers If the stimulating agent is withdrawn gently without disturbing the position of the patient's fingers no tightening of the grasp results but his hand and arm sometimes move through space (grope) in the direction of the moving object, as if drawn by a magnet

2) When an object is placed in the involved hand of the patient the fingers close slowly and gently around it, but any attempt made by the observer to withdraw the object may evoke a grasp reflex in which the object is grasped more firmly Nevertheless, when the patient clenches his empty fist he can relax the fingers again without difficulty

3) Any attempt to bend the arm or leg is met by an active resistance exerted by the antagonistic (stretched) muscles, this differs from the resistance offered by the ordinary spastic limb in that there is no sudden giving way with a "clasp-knife effect "

The gentle grasp and the groping movements just described (see *1*) above) are voluntary and not reflex acts Although they are automatic in nature and are taken to indicate deterioration of the psychomotor functions, the patient can prevent their occurrence if asked to do so They disappear in stupor or in coma The gentle grasping movement follows tactile stimuli alone or visual and tactile stimuli acting together The groping movements can be elicited by visual stimuli alone but not by tactile stimuli alone

These responses have also an involuntary component that depends upon a *tonic innervation* (Walshe and Robertson, 1933), originating as stretch reflexes The strong grasp when an attempt is made to remove an object from the hand is an example of this reflex It is quite distinct from the gentle grasp movement, and results from the passive stretching of the flexor muscles of the fingers as the observer attempts to extricate the object The patient cannot relax the grasp and release the grasped object It occurs in the unconscious patient The grasp reflex is most pronounced when the patient is on his side and the affected arm uppermost

Richter and Hines (1934) produced the "tonic grasp reflex" in adult monkeys by removal of area 6 Excision of the motor areas or the prefrontal areas from both hemispheres did not cause the effect A similar reflex is present in normal infants, it is sufficiently strong to suspend the body from a bar for 2 min A grasping reflex has also been described

for the foot in lesions of area 6, it occurs in the normal infant up to the end of the first year and is elicited by stroking the sole

Other Prefrontal Areas *Area 8*, called the *frontal eye field*, lies in front of area 6 Stimulation of the cortex here causes a conjugate movement of the eyes and turning of the head to the opposite side, opening and closing of the eyelids, and sometimes dilation of the pupils and lacrymation No visual hallucinations occur in man, but an epileptiform seizure may be provoked which spreads to the adversive field (area 6) Ablation of area 8 of one side in monkeys or involvement of this area or its projection fibers in man causes the eyes to be turned up toward the side of the lesion, and paralysis of the conjugate eye movement These effects are temporary The animal in walking will circle toward the side of the lesion No abnormalities are observed in the pupils or in the movements of the lids This area receives fibers from the dorsomedial nucleus of the thalamus, through which it is connected with the hypothalamus It also connects by long association tracts, both afferent and efferent, with the occipital lobe (visual area, 18) and with the tegmentum of the midbrain (probably with the oculomotor nuclei)

Area 44 in the region of the posterior part of the frontal operculum in the *dominant hemisphere* (which is the left in right-handed persons) is the motor area for speech (Broca's area) Stimulation of this area in conscious patients causes their speech to be abruptly arrested Cortical mechanisms of speech are discussed in chapter 8

PREFRONTAL OR ORBITOFRONTAL REGION

The prefrontal region embraces the part of the frontal lobe in front of areas 8 and 44, but it includes the orbital as well as the lateral aspect of the lobe, and for this reason is also known as the orbitofrontal region (Brodmann's areas 9, 10, 11, 12, 13, and 14) These areas were once thought to be inexcitable, and were therefore referred to as "silent" or association areas But upon stimulation by a suitable electric current having pulses of low frequency, autonomic, respiratory, circulatory, renal, and gastrointestinal responses can be elicited After bilateral removal of these areas the blood pressure is reduced, gastric secretion suppressed, and gastrointestinal movements increased In man, suffering from intractable pain is relieved These areas receive important fibers from the dorsomedial nucleus of the thalamus (Fig 9 100), which in turn receives impulses from the hypothalamus These orbitofrontal areas, especially those of the orbital surface, are also closely associated with the "limbic system," as described later

Area 24, anterior part of the cingular gyrus on the mesial aspect of the hemisphere, is a powerful suppressor area Various autonomic responses follow stimulation of this area including pupillary dilation, piloerection, acceleration of the heart, and a fall in blood pressure Arrest of respiration in expiration also results

Unilateral or bilateral removal of the *prefrontal area* does not cause paralysis either in the monkey or in man *Unilateral* removal of a human prefrontal area produces a definite if rather subtle alteration in mental processes Some loss of initiative and mental alertness are the most outstanding results of the operation Memory, judgment and intellect often

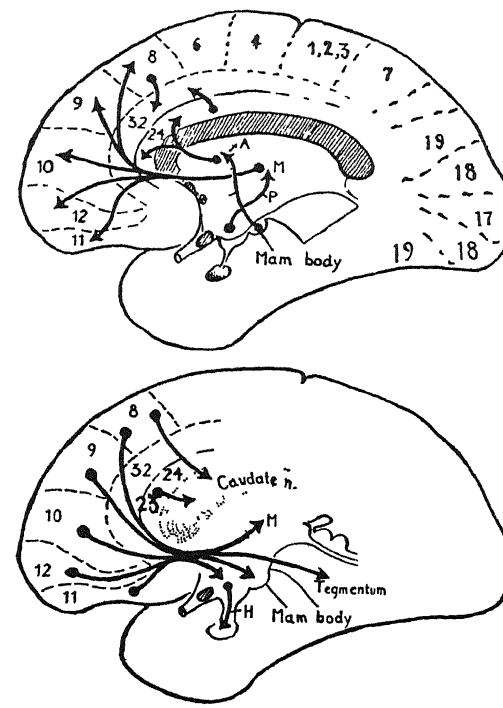

Fig 9 100 Afferent (*upper*) and efferent (*lower*) connections of prefrontal cortex seen from medial view *A* and *M* are anterior and dorsomedial nuclei of thalamus *H* is hypothalamo-hypophysial tract *P* is the periventricular system of fibers

show little or no deterioration Removal of the prefrontal area of the dominant hemisphere (i e , the left in right-handed and the right in left-handed persons) is sometimes thought to produce somewhat greater alterations in character or intellect than does a similar operation upon the nondominant side Even the *bilateral* excision of prefrontal areas is followed by a surprisingly moderate mental defect, so far as superficial observation and examinations are concerned The fact that following a unilateral or even a bilateral prefrontal lobectomy a patient may appear to be normal, however, and functions as a normal individual during casual associations, or passes the usual psychometric tests with flying colors does not mean that the frontal lobes are without important functions so far as mental activity and behavior are concerned If suitable testing is done, it is possible to determine with amazing accuracy the damage to the frontal lobes (Halstead, 1947) Many of these tests are based upon the ability of the patient to classify and categorize a large number of familiar objects and to recall them once they have been taken from him

In an operation for the eradication of a tumor, Dandy excised the frontal lobes on both sides in front of the motor areas (reported by Brickner, 1934) The subject of this extensive extirpation appeared to be of normal intelligence upon a casual acquaintance It is reported that for an hour he toured the hospital with two visiting neurologists who failed to notice in him any mental abnormality A more intimate knowledge of the patient, however, revealed very definite changes of character and mentality His mental age was about 13 years, his intelligence quotient 80 The main features shown by this subject can be taken as generally representative of the effects of extensive prefrontal destruction They constitute what has been called the *frontal lobe syndrome*, as follows

1) *Lack of restraint* leading to boasting, self-aggrandizement, hostility, aggressiveness

2) *Distractibility* and *restlessness*, with difficulty in fixing attention

3) *Hypermotility* which appears to be due to the loss especially of area 13 on the orbital surface

4) *Flight of ideas*, puerile fantasies, emotional instability, facetiousness, punning

5) *Lack of initiative*, and difficulty in planning any course of action

6) *Impairment of memory* for recent events but not for remote events

7) *Impairment of moral and social sense*, loss of love for family

8) *Failure to realize*, or indifference to, the seriousness of his condition, and a sense of well-being (euphoria)

Another manifestation which may follow a prefrontal defect is a disturbance of orientation in time and space The classical example of a severe prefrontal injury which resulted in surprisingly little mental defect, is the case of the American, Phineas Gage (1848), who suffered extensive damage of his frontal lobes by an iron tamping bar driven through his head by an explosion The bar penetrated the left orbit and emerged from the midline of the head just anterior to the coronal suture He was stunned for only an hour and was able with assistance to walk to a surgeon's office He lived for 12 years after the accident and showed in general these mental changes

Chimpanzees which have had both prefrontal areas removed show restlessness and are easily distracted, although they remain alert and evince a keen interest in things around them Fulton and Jacobson reported in 1935 (see Fulton, 1951) that after this operation chimpanzees failed to show temper tantrums and other manifestations of frustration when they made errors in tests requiring the solving of problems or puzzles This observation formed the basis for surgical attempts to relieve certain psychoneuroses in man, first employed by the Portuguese neurologist, Egaz Moniz (1936) The operation, called *frontal lobotomy*, consists in severing the fibers connecting prefrontal areas with subcortical centers (probably the thalamus and hypothalamus) More recently, with the introduction of the various drugs capable of reducing nervous tesnion and rendering an aggresive, agitated patient more tractable, the use of this type of operation has been greatly diminished

Frontal Lobes and Intelligence. The development of the frontal lobes bears in general a direct relationship to the level of an animal in the phylogenetic scale and to its "intelligence " This circumstance has led to the concept that this part of the cerebrum is the seat of the intelligence of animals and the "center" or "organ" of the mind of man Controlled observations, however, indicate that the concept is not valid Following World War II it

was possible to study the effects of traumatic prefrontal injuries in a previously normal population of men with known preinjury intelligence test scores on the Army General Classification Test (AGCT) Administration of the AGCT to these men 10 years after injury showed no decline in their test scores (Weinstein and Teuber, 1957) It seems clear, therefore, that destruction of the prefrontal region does not produce any notable deficit in intelligence

It seems probable that the prefrontal area represents a region of relatively high associative or synthetic capabilities, required for the formulation of abstract ideas and accurate judgment, and for the guidance of conduct in conformity with social customs Here also are mainly located those mental processes relating to "prediction," forecasting, or to any planned action A person deprived of these areas may have little ability as a strategist, thus, a housewife after the loss of these parts of the cortex experiences some difficulty in planning a meal Mental capacity according to this conception is a function of the cerebral cortex as a whole rather than of any particular region (Lashley, 1929)

Lateralization of Function

Because the central nervous system seems to be bilaterally symmetrical in its organization, and also because the cranial and spinal nerves innervate sensory or motor structures on one side of the body or the other, it is of some interest to inquire to what degree the two halves of the system are independent, and where they are necessarily interrelated At the level of primary sensory input and final motor output the two halves are all but autonomous, except for the fact that interconnections occur in spinal cord and brainstem such that the activity of the two halves is naturally integrated For example, ipsilateral flexor reflexes are accompanied by contralateral extensor reflexes (chap 4) Moreover, there are many loci where artificial stimulation yields essentially bilateral responses Thus, Karplus and Kreidl (1910) and also Magoun et al (1938) noted that the autonomic responses elicited by hypothalamic stimulation are bilateral, as are respiratory and other responses evoked from pontile and medullary tegmentum Commissural fibers across the midline of cord and brainstem are plentiful, more than sufficient to account for these results

Similarly, in the cerebrum the commissural fibers from one side to the other are one of its principal anatomical features Most of these fibers run in the corpus callosum, already mentioned as a component of the central white substance of the hemispheres Lesser numbers

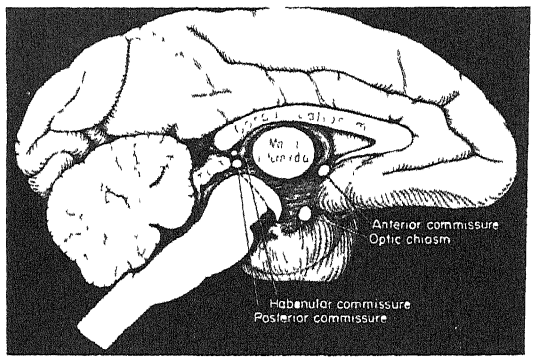

Fig 9 101 Midsagittal aspect of monkey brain showing main structures involved in surgical bisection (Sperry 1962)

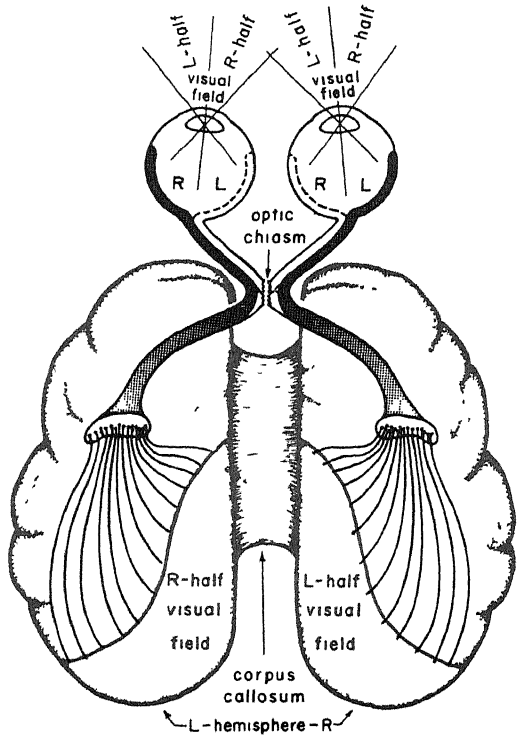

Fig. 9 102 Sketch indicating effects of midsagital division of optic chiasma (Sperry 1961)

are found in smaller bundles, including the anterior and suprachiasmatic commissures rostrally, and the posterior and habenular commissures caudally, with perhaps the massa intermedia that unites the two halves of the thalamus (Fig 9 101)

Some 15 years ago, Sperry and his associates at the California Institute of Technology (see Sperry, 1961) began a study of deficits in animals in which the principal commissures of the cerebrum had been sectioned at surgical operation At the time of initiation of their research the function of the corpus callosum with its multitude of fibers was unknown They were able to study what happens when it is cut because of the imaginative character of the tests they employed, most of them based upon the fact that the visual system is lateralized in its central connections Fibers that leave the retina to form the optic nerve partially decussate in the optic chiasm (sect 8, chap 4) As a result of this partial crossing the right side of the visual field, after registration upon the left half of each retina, is represented in the left lateral geniculate body and striate cortex, whereas the left half of the visual field is carried to the right side of the cortex (The fovea is represented bilaterally) If the fibers that cross in the optic chiasm are cut, and if one eye is then covered, all visual sensation must be achieved in the cortex of the side of the brain on which the eye is functioning (Fig 9 102) This makes it possible to make sure that visual information is reaching only one cortex, depending upon which eye is covered

In their early experiments they discovered (Myers, 1959) that cats tested after section of the optic chiasm and with one eye covered were able to translate visual information to one side of the cortex into control of both sides of the body If the animal learned to perform a certain test with the right eye uncovered, it could do the same test with only the left eye uncovered When the major commissures were then cut at a second operation, however, including the corpus callosum, the animal lost the ability to transfer learning from one side to the other A task learned with one eye open proved to be a new task when presented via the other eye Later experiments on monkeys, baboons, and chimpanzees have in general confirmed the results obtained on cats They have shown, however, that the two halves of the cortex are not completely independent, after section of the corpus callosum and the major commissures either hemisphere is able to control either forelimb for either learned or unlearned behavior, presumably via crossing fibers in brainstem and spinal cord

Similar observations have been made upon a limited number of human patients who have required operations in the region of the corpus callosum Their most notable deficit concerns speech, writing and language, where both the input and the output portions of the systems are lateralized Speech and related activities, such as reading and writing, are represented mainly in the cortex of one hemisphere (chap 8, p 9–158) This has been known for centuries, inasmuch as cortical lesions of one side of the brain may affect speech, whereas similar lesions on the other side leave it undisturbed The usual teaching is that the speech mechanisms are in the cortex of the side that controls the preferred hand—the so-called "dominant" hemisphere For right-handed persons this is the left cortex Penfield and Roberts (1966), however, decided that speech is usually controlled from the left hemisphere no matter which hand the individual uses for skilled actions Whatever the side, it is lateralized

This lateralization of speech makes it possible to test for interconnections between the two halves of the cortex in human subjects After section of the corpus callosum, if the subject with one eye covered is asked to fixate his vision on a point, brief stimuli can then be applied to other positions in his visual field so that information is conveyed to only one of the visual cortices Whether or not he is able to respond to this information via speech, writing, or tests of comprehension is a test of interconnections between the two sides Under these conditions a patient may be unable to name objects that he sees in the left half of his field of vision, the half that is transmitted to the right visual cortex According to Gazzaniga (1970), this type of defect is also exhibited with reference to position sense when a subject is asked to describe the location of his left wrist, fingers, or toes

7 CONTROL SYSTEMS THAT ESTABLISH REGULATIONS

Many sections of this textbook contain descriptions of systems by which the several physiological processes are governed Neural and endocrine control of digestion, for example, is reviewed in the appropriate context (sect 2, chaps 2 and 3) Similarly, the control of circulation and of respiration is outlined where these topics are discussed (sect 3, chap 9, and sect 6, chap 4, respectively) Other examples are found in other sections of the textbook, including almost the whole of the treatise on endocrinology (sect 7) If control systems are as common in physiology as this brief listing implies, perhaps it may be instructive to bring together what is known about them so as to try to discover whether they have any general characteristics (see Yamamoto and Brobeck, 1965, Yamamoto, et al , 1969)

Throughout this textbook the word, *control*, has been used with a meaning practically identical with its general English meaning *Regulation*, on the contrary, is used technically to designate the maintaining of relative constancy of a variable by a system that includes a *detector* for the variable or some derivative of it, and a *negative feedback* of information from the detector to the controller mechanisms (chapt 1, p 9-18)

Typical Regulations

As Figure 9 103 illustrates, the several regulations of the body do have features in common, and can be diagrammed in a similar manner On these diagrams each noun or phrase is a variable that can be measured, either physically or chemically, or as a sequence of nerve impulses having a demonstrable frequency, duration and pattern The arrows do not have a mathematical significance here, they simply mean, "is accompanied by," "leads to," "causes," or "brings about"—that is, they denote a certain logical relationship in time Thus, a decrease in the cardiac output is accompanied by (or causes) a decrease in stretching of aortic walls, and this in turn leads to (is accompanied by or brings about) a decrease in the output of stretch detectors in the aortic wall and carotid sinus In these diagrams the nature of the central computational processes is not specified They are represented by Sherrington's term, *integration*

The similarities in these diagrams arise from a few basic principles of neural and endocrine physiology, as follows

1) The nervous system controls contraction of all smooth and striated muscles, and the secretion of exocrine glands

2) Both the nervous and endocrine systems function to give control at a distance, e g , by way of a digital-like transmission, the nerve impulse

3) The computation processes of the nervous system are brought about through infinitely graded degrees of stimulation or inhibition, (although synaptic transmission per se is quantal, see Katz, 1971)

4) Higher controls tend to be more complex than lower ones

5) No one type of control is independent of all others Thus, the overall pattern of controls includes priorities and compromises,

6) The creation of a control loop by introduction of feedback from detectors may convert a control into a regulation

The endocrine control systems share many of these characteristics, including the property of infinitely graded degrees of stimulation This particular property is a function of the cell membrane Moreover, many otherwise endocrine systems have at some stage a neural link, and vice versa For example, many of the endocrine mechanisms can be traced backward towards the origin of the control signals, back to the level of either the posterior or anterior lobe of the pituitary gland, which themselves are under the control of the hypothalamus—a neural control for the posterior lobe, and a neuroendocrine control for the anterior (Harris, 1955) The neurons that maintain these controls are presumed to accept neural input from other regions of the brain and spinal cord, and

Fig 9 103 Diagrams that illustrate how a change in the magnitude of a physiological variable becomes a change in potential that is detected by specialized cells They send signals to the nervous system as a result of which an effector response is created to alter the magnitude of the variable in an opposite direction This in turn alters the potential and hence the signal from detectors A simple feedback loop of this type will usually show oscillation

to convert this input into neural or endocrine messages transmitted to the lobes of the hypophysis (Fig 9 104) The hypothalamic neurons, therefore, are neuroendocrine transducers (Wurtman, 1970) They have also another interesting property, in that they are sensitive to the concentration of pituitary hormones, perhaps in a specific fashion appropriate to the nature of the system they control They may be sensitive also to more general changes, such as osmolarity, thermal gradients, or biochemical changes If their function is altered by, for example, the level of a circulating hormone, they may be designated as two-stage transducers, humoral-neural-humoral In the examples that at present are best known, the first of these stages is a negative feedback For example, ovarian steroids seem to act upon the hypothalamus to suppress neuronal activity, and hence the secretion of hypothalamic releasing substances, that ordinarily enhance secretion by the anterior pituitary gland

One other property of these systems should be noted The hormones of the endocrine system not only have specific actions upon their control systems as feedback loops, but they also have metabolic or other actions upon neurons in general This means that in the absence of a hormone, thyroxine, for example, many portions of the neural axis may show abnormal function Similarly, there is reason to believe that sex steroids have specific actions as negative feedback upon control neurons in the hypothalamus, but also more generalized effects along the neural mechanisms responsible for behavior These possibilities of interaction and control can be summarized by two statements, as follows

1) The central nervous system can exert a quick control of effector systems via neural messages, and also a slower and more prolonged control of certain organs by way of the endocrine glands

2) Similarly, the nervous system may gather information quickly from neural detectors, or in a slower and more prolonged fashion from the action of hormones or the influence of other types of generalized changes directly upon neuronal membranes and/or synaptic mechanisms

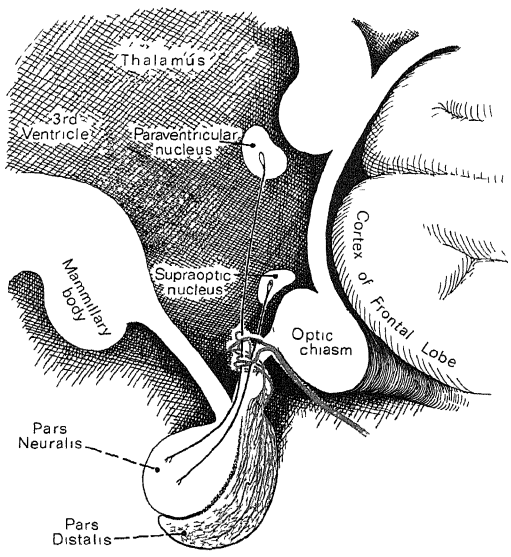

Fig 9 104 Drawing from photomicrographs of sagittal section through hypothalamus and pituitary gland where blood vessels have been injected with India ink Vessels that run along inferior surface of hypothalamus enter median eminence then contribute their blood to portal vessels distributed to pars distalis (anterior lobe) This portal system transports hypothalamic neurohumors to the pituitary gland

CIRCULATION

As Detweiler has indicated (sect 3), the quantities regulated in the circulation are arterial blood pressure, which is monitored as stretching of elements in walls of major arteries, and adequacy of blood supply in certain peripheral tissues, monitored as CO_2 tension (and pH) in, for example, skeletal muscle The latter, the constancy of local blood supply, is maintained almost entirely through local, presumably non-neural mechanisms that alter smooth muscle tone of small blood vessels in response to accumulation of carbon dioxide The general arterial blood pressure, by contrast, is preserved through a variety of mechanisms that control the following *a*) the force and frequency of the heart beat, and thus the cardiac output, *b*) the tone of vessel walls, both in arteries and veins, *c*) the degree of opening of arterioles through which blood flows out of the arterial system (this is the "peripheral resistance"), and *d*) mechanical forces such as the action of gravity, the contraction of skeletal muscles, and the magnitude of intrathoracic pressure, that affect the return of blood to the heart These mechanisms are controlled in large part by the autonomic nervous system, with participation of the somatic system and skeletal muscle, as in exercise, for

example, or in changes of posture There is interaction of these controls with those of other systems Thus, blood gas partial pressures affect the circulation as well as pulmonary ventilation by way of detectors in the carotid and aortic bodies

As noted in an earlier chapter, these peripheral mechanisms can be stimulated artificially in the medulla oblongata This is the level where the several reflexes are processed in regions known, respectively, as the cardiomotor, vasopressor, and vasodepressor mechanisms or "centers" They are resident in the reticular formation Similar stimulation evokes circulatory changes from hypothalamus, and from prefrontal or orbital areas of the cerebral cortex (p 9–127) It is the hypothalamic localization that is believed to be responsible for circulatory changes during exposure to heat or cold, and for those associated with emotional expression in decorticate animals The hypothalamus is also regarded as having an important role in the changes that occur in circulation during exercise (Folkow and Rubinstein, 1965) The higher levels including the limbic cortex (p 9-156) perhaps interact with the hypothalamus during emotional experience They may well serve also as components of feedback loops when exercise is initiated by cortical mechanisms One sees, therefore, that the circulation is controlled by a complex of mechanisms distributed almost the full length of the neural axis (Korner, 1971)

RESPIRATION

Control of pulmonary ventilation depends upon the sensitivity of peripheral and central detectors to partial pressures of carbon dioxide and oxygen, and is effected through changes in respiratory minute volume—that is, changes in respiratory frequency and depth (von Euler et al, 1970) (Fig 9 103) Any illusion that the system is a simple one begins to disappear, however, when one moves from consideration of peripheral to central mechanisms The nature of the central interaction of chemodetectors and the pulmonary stretch receptors is not fully understood, although it is known to take place in the medullary reticular formation, presumably upon the membranes of inspiratory neurons Moreover, the problem of how the respiratory rhythm is generated in the first place is unsolved As already noted, one possibility is that it represents a signal generator function of central neurons, in which a train of impulses is modulated so as to create a second order rhythm by way of feedback loops (chap 1, p 9–18) Control of pulmonary ventilation also interacts with other controls, for example, panting is a respiratory response to thermal stress Other interrelations are apparent during speaking, singing, or playing of a wind instrument, as well as with exercise and in sleep

Another characteristic of the control of pulmonary ventilation is the powerful behavioral reactions that can be evoked as part of it Consider, for example, a subject with his nostrils and mouth forcibly covered, or a subject held involuntarily under water, or in the presence of a gas such as ammonia, formaldehyde, or HCl The behavioral component of the regulation may supersede all other kinds of behavior The significant point is that regulations are not only automatic, involuntary, and reflex They may command the highest levels of the nervous system and include a great variety of patterns of behavior In the case of pulmonary ventilation, whereas the peripheral mechanisms and the reflex connections are reasonably well known, and the properties and location of the brainstem neurons can be described in some detail, the genesis of the behavioral reactions is all but unknown

WATER BALANCE

Hypothalamic mechanisms control both the rate of water loss through the kidneys and the rate of water ingestion in drinking Water loss was the first of these to be analyzed experimentally (sect 5, chap 1) A disorder of this control has been known for centuries, the condition named diabetes insipidus, where a patient involuntarily excretes a large volume of dilute (i e, "insipid") urine, and in compensation drinks a large volume of water daily Early experiments did not disclose the nature of the diabetes, because it was assumed that the effective lesion would prove to lie either in the hypothalamus or in the pituitary gland Later experiments showed that both structures are involved (Fisher et al, 1938), because secretion of the antidiuretic hormone in the posterior lobe is controlled by neurons of the supraoptic nucleus (sect 7, chap 3) By perfusing the base of the brain with blood having an osmotic pressure either higher or lower than normal, Verney (1947) and others demon-

strated that this region contains a mechanism sensitive to water concentration in the extracellular fluid Whether the detector is, in fact, neurons of the supraoptic nucleus, or whether it lies near these neurons, or whether it is elsewhere and projects to these neurons is not entirely clear Cross and Green (1959), as well as Brooks and his associates (Koizumi, et al, 1964), have recorded changes in single unit activity from this nucleus in correlation with changes in osmolarity (Figs 9 105 and 9 106) Moreover, cats with the hypothalamus removed except for an "island" that includes the supraopticohypophysial system do not exhibit diabetes insipidus (Woods and Bard, 1960) In any event, for control of water loss via the kidney this system is one that has two stages of transduction First, there is transduction of water concentration ("activity") into nerve impulses, second, there is transduction of this neural activity into secretion of the antidiuretic hormone (Dreifuss et al, 1971)

A second kind of transduction evidently occurs within the major blood vessels, especially the right atrium, where changes in hydrostatic pressure bring about changes in secretion of antidiuretic hormone (Henry, et al, 1956, Share, 1968) By these two systems the rate of water loss is made to vary in response to changes in the concentration of water in the extracellular fluid and the volume of this fluid as reflected in changes in central venous pressure

Water Intake. For control of water intake the system contains additional detector mechanisms and reflexes The first of these begins with perception of dryness in membranes of mouth and throat, as suggested by Cannon (1918) and later more fully described by Epstein and his associates (1964) The latter have found in rats that interruption of salivary ducts and extirpation of salivary glands leads to a condition where the animals must necessarily drink when they eat dry food, even though their general bodily state may not require water A second mechanism is the water concentration in fluids of the body, and a third originates in the pressure-sensitive neurons of the great veins, as in the control of secretion of the antidiuretic hormone The fourth and last is a mechanism recently discovered by Fitzsimons (1969) He observed that the amount of water drunk by nephrectomized rats is less than that taken by animals with occluded ureters, when conditions that induce drinking are imposed upon the animals From this he concluded that the kidney is placing in the circulation something that facilitates drinking The material that does this is renin, the enzyme that produces angiotensin II The most recent experiments have shown that angiotensin II induces drinking when it is perfused directly into the hypothalamus (Fig 9 107)

Lesions in the lateral hypothalamus abolish drinking (Montemurro and Stevenson, 1955 and 1956), except that arising from dryness of the mouth (Epstein and Teitelbaum, 1964) The latter can be interrupted by section of appropriate cranial nerves The ingestion of water is a more complicated form of behavior than those normally responsible for ventilation and other similar regulations It may involve really heroic effort for securing of water (Wolf, 1958), or it may be as simple as the turning of an animal's head to a water spout for a brief period of lapping At some level in the neural

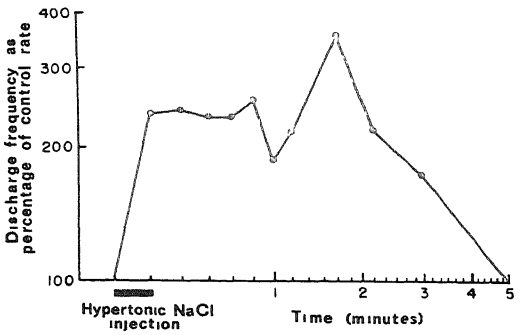

Fig 9 106 Increased frequency of discharge of neurons of supraoptic nucleus (*ordinate*) during and after intracarotid injection of hypertonic sodium chloride solution (0 5 ml of 1 M NaCl solution) (Koizumi et al 1964)

or neuroendocrine circuits some completely unknown mechanism creates an awareness of need for water At any instant, for example, any adult subject can state whether or not he feels thirsty This awareness is presumed to require cortical function, but there is no evidence as to the nature or locus of this highest level component In the hierarchy of mechanisms for regulation, water balance is somewhere near the middle The body cannot sacrifice either circulation or respiration as a device for preserving water balance, yet water is more vital to the body than temperature regulation, energy balance, or reproduction

ENERGY BALANCE

Still more complicated than the regulations heretofore described is the preservation of energy balance This is assumed to be a regulation because of the constancy of its end product—body substance as measured by the body weight of an adult subject Mechanisms of gain of energy are known, in higher animals they are solely by way of food intake Mechanisms of energy loss are more diverse Energy can be lost as heat, or as work in a truly physical sense—i e , in raising a weight or giving it a momentum Or energy can be stored within the body in the form of protein during growth or recovery from starvation, as carbohydrate (glycogen) during recovery from a brief fast, or as fat in almost unlimited quantities Because each of these categories of processes has been studied for many years, a large amount of information is available about all of them This

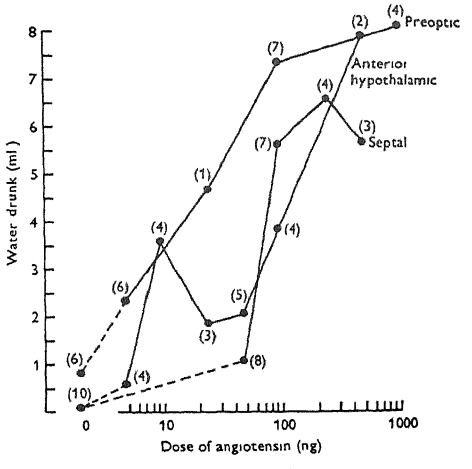

Fig 9 107 Water drunk (*ordinate*) by three rats as a function of amount of angiotensin (*abscissa*) injected intracerebrally (Epstein et al 1970)

BODY WEIGHTS, FOOD INTAKES AND FINAL BODY FAT CONTENTS OF PREVIOUSLY FORCE FED RATS ALLOWED ACCESS TO FOOD

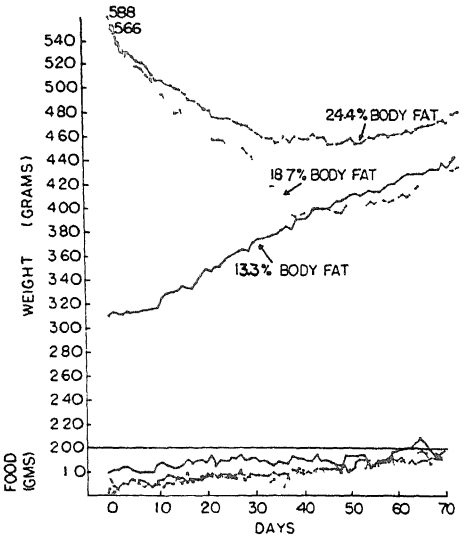

Fig 9 108 Two rats (566 588) that had been made obese by forced feeding ate a reduced amount of food when they were fed ad libitum until their body weight and estimated body fat concentration returned to the normal levels (Cohn and Joseph 1962)

is not the kind of information needed, however, to account for preservation of energy balance. What is needed is a knowledge of how the body—with variable levels of work output, under variable conditions of environmental temperature and humidity, yet at a given age and growth potential—how the body under these circumstances manages to adjust food intake so that body weight changes slightly or not at all

The possibility that there is some overall system for this regulation is suggested by a few but convincing observations First, there is the common experience of adult men who find that their body weight is almost constant in spite of variations in activity, and often in the face of efforts to gain or lose Second, experiments by Cohn and Joseph (1959) proved that animals made obese by overfeeding would not eat a normal quantity of food until their body weight had returned to the control level (Fig 9 108) Third, lesions in the hypothalamus may cause a failure of feeding (Anand and Brobeck, 1951), or hyperphagia and obesity (Tepperman et al , 1941) Fourth, injury to the hypothalamus will profoundly alter regulation of body temperature, and thus the energy converted into heat and lost from the body (see later in

this chapter) Fifth, there is evidence that injury to the hypothalamus or the brain just ahead of it will either increase or decrease motor output as locomotion

What has been said about the results of hypothalamic injury can be said in most instances in reverse about hypothalamic stimulation For example, if a lateral hypothalamic lesion abolishes feeding, stimulation of the lateral hypothalamus will induce feeding (Leibowitz, 1971) Again, if locomotor activity is abolished by lateral hypothalamic lesions, it may be induced by electrical stimulation of this part of the brain

How the hypothalamus, either independently or in collaboration with the limbic system, rhinencephalon, or other parts of the brain, integrates all of the processes required for energy balance is unknown At least three kinds of "sensation" are created—hunger-satiety, warmth-cold, and tired-rested Receptors for the warm-cold pair are found in the skin and oronasal membranes, as well as in the rostral hypothalamus or preoptic region Where the other kinds of detection occur is not certainly known With reference to the hunger-satiety state, the possibilities under consideration include the gut, liver, and hypothalamus (see sect 2, chap 1)

Regulation of Body Temperature

The temperature of many warm-blooded (*homoiothermic*) animals remains practically unchanged although the surrounding temperature may vary between 0° and 50° C or upward On the contrary, the body temperature of a cold-blooded (*poikilothermic*) animal such as a frog, turtle, etc , is practically that of its environment during laboratory tests (Fig 9 109) In natural conditions these latter animals preserve an almost constant temperature by behavioral responses that include migration and hibernation

The normal human body temperature recorded from the mouth is usually given as 37° C, with the rectal temperature one degree higher The figure varies between individuals, ranging from 35 8 to 37 8° C orally Variations also occur in any one individual throughout the day—a difference of 1 0° or even 2 0° C occurring between the maximum in the late afternoon or early evening, and the minimum between 3 and 5 o'clock in the morning Temperature of the several regions of the body depends upon whether they are major sources of metabolic heat (e g , liver, heart), or locations where heat is given off (e g , skin, upper respiratory tract) (Fig 9 110) Strenuous muscular exercise causes a temporary rise in body temperature that is proportional to the severity of the exercise, the level may go as high as 40 0° C

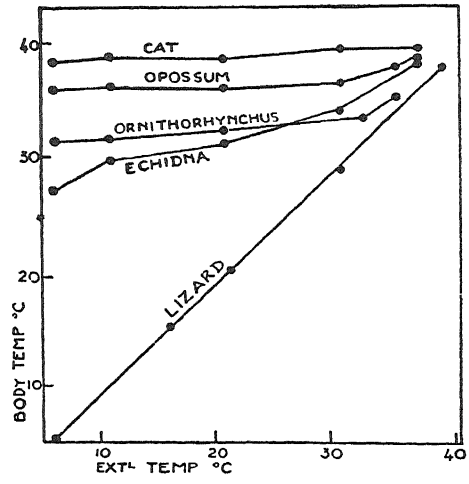

Fig 9 109 Body temperature of five species of animals as a function of environmental temperature Duration of each exposure was 2 hr (Martin 1930)

Stability of body temperature varies with the size of the body In small animals or in human infants where metabolic rate is relatively more intense and surface area relatively greater, the oral and even the rectal temperature may vary through a range perhaps twice that of larger animals or human adults This reflects certain principles of the physics of heat storage and loss, rather than any inherent difference in the regulating system In a small body the amount of heat "stored" is a smaller fraction of the metabolic rate than in larger individuals In the latter the stored heat provides an "inertia" that tends to counteract thermal changes Heat storage is a function of thermal capacity, which varies with body mass, heat loss, by contrast, varies generally with surface area The most lucid account of these and other aspects of thermal exchange is the one in Kleiber's monograph (1961)

Under basal conditions when no external work is being done, all the metabolic energy ultimately appears as heat, and amounts to approximately 1 kcal /kg of body weight/hr

Since the body is composed chiefly of water, and has a specific heat of a little less than one, the body temperature would rise about 1° C/hr if no heat were lost externally With strenuous physical exertion more than three-quarters of the increased metabolism appears as heat within the body, the remainder is converted either to work or to heat in the external system Fever increases the metabolic rate by some 13% for each degree rise in mean body temperature (C) This change in metabolism corresponds to a temperature coefficient (Q_{10}) of between 2 0 and 3 0 overall

The body's heat-regulating mechanisms are supposed to be in abeyance below an internal temperature of about 23° C, because the underlying neural mechanisms are suppressed The body then gains or loses heat like an inanimate object The lower lethal temperature for the human is about 26° C, although lower temperatures have been induced with survival during therapeutic hypothermia Death is due to cardiac failure The upper lethal limit is not clearly defined, cases are recorded to have recovered after attaining a rectal temperature of 43 5° C Probably the average upper limit is about 43° C

HEAT LOSS

Heat is lost from the body through *a*) radiation, conduction, and convection from the skin, *b*) warming and humidifying of inspired air, *c*) evaporation of sweat and insensible perspiration, and *d*) via urine and feces Of these several routes only *a*) and *c*) are directly under physiological control Radiation is responsible for about 50% of the total heat loss and convection for about 15% (Table 9 6) Urine and feces account for only about 2% or less of the total heat loss Most of the remainder (about 30%) is lost in the evaporation of water These percentages are given for an average man doing light work with an overall energy exchange of about 3,000 kcal /day

Radiation. The rate of cooling of any object varies with the thermal gradient between its surface and objects in its environment This gradient can be altered by physiological mechanisms that change skin temperature These mechanisms include the following adjustments in the blood-vascular system

a) *Redistribution of Blood* By redistribution of blood flow the temperature of the skin may be adjusted from any temperature from about

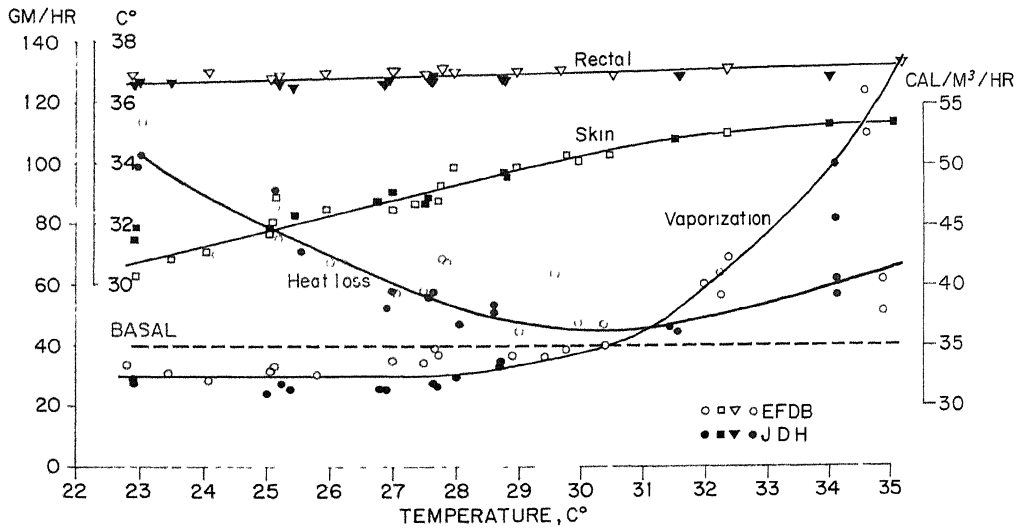

Fig 9 110. Graphs showing the influence of environmental temperature upon rectal and skin temperature (with mean body temperature derived arithmetically from them) Metabolic rate rises during cold exposure mainly as a result of shivering Vaporization rises in the heat mainly because of sweating Crosbie et al 1961 replotted

15° C (during cold exposure) up to the central body temperature At ambient temperature of 34° C the quantity of blood circulating through the skin may be as great as 12% of the cardiac output (DuBois, 1939) Scott, et al (1940) found that blood flow to the fingers could increase from 1 ml /min /100 gm of tissue to a figure of 80 or 90 ml /min upon exposure to heat Fingers, therefore, serve as highly efficient radiators of heat

b) Variations in Blood Volume An unacclimatized man is capable of increasing total circulating blood volume by about 10% in 2 to 4 hr on exposure to heat of severity sufficient to cause a diffuse cutaneous vasodilatation The blood is diluted by fluid drawn into the circulation from the tissues, chiefly the skin, muscles and liver, cells are added from the spleen Hematocrit drops and concentration of plasma protein decreases The reverse changes occur during exposure to cold A sudden transition from a warm to a cool environment causes a rapid decrease of blood volume associated with a marked diuresis

c) Increased Circulation Rate An increased cardiac output ensures a rapid blood flow through the dilated cutaneous vessels This increase and the enhanced blood volume promote the transportation of heat from the interior to the surfaces of the body and so enhance the loss of extra heat

With reference to radiation of heat or infrared radiation, the human skin of whatever "color" functions as a nearly perfect "black body" in the physical sense (Hardy, 1949) In a standing posture about 85% of the total skin area is exposed for heat radiation, the remainder being the opposed surfaces of, e g , axillae and other similar regions of the body The percentage exposed is increased during heat stress and decreased in the cold by postural changes Clothing modifies radiant heat loss by altering the temperature of the surface where the heat exchange is occurring

Convection The most important factor influencing heat loss by convection is air movement For any given air temperature the loss increases with the square of the wind velocity up to 60 m p h , beyond this velocity there is little further increase

Evaporation of Water. It is obvious that the nearer the temperature of the environment comes to that of the blood the smaller will be the amount of heat lost by radiation and convection Above an ambient temperature of 38° C the body gains heat by radiation from the environment This heat is then dissipated, together with heat produced within the body, by processes in which water is converted from a liquid to a vapor state at surfaces of the body The heat absorbed in evaporation of 1 ml of water amounts to 0 58 kcal Even at ordinary room temperatures when there is no obvious perspiration, the heat lost through evaporation from the lungs and skin amounts to about 17 kcal /hr This is approximately one-fourth of the basal heat production About two-thirds of this is lost from the skin as insensible perspiration, the remainder from respiratory passages At higher temperatures the proportion of heat lost by vaporization of water, mainly from the skin, increases dramatically, so that at ambient temperatures above 35° C it accounts for nearly all of the heat lost (Fig 9 110)

In animals that pant a comparable increase in vaporization occurs via the respiratory system Rats enhance their heat loss by spreading saliva upon their fur (Hainsworth, 1967) The rate of evaporation of this water is influenced inversely by the degree to which the atmosphere is already saturated with water—by its relative humidity This is why sweat drips instead of evaporating when the ambient air is humid A man can maintain a normal temperature in an atmosphere of over 100° C provided the air is perfectly dry On the other hand, in a damp atmosphere a temperature of 50° C causes body temperature to rise rapidly

Sweating. Sweat is a weak solution of so-

dium chloride in water, together with urea and small quantities of potassium ion, other electrolytes, and lactic acid It has a specific gravity of from 1 002 to 1 003, and a pH varying from 4 2 to 7 5 The concentration of NaCl varies from 50 to 100 mEq /liter When sweating is profuse the concentrations of electrolytes rise towards the higher of these values, whereas with acclimatization the percentage is said to decline Nevertheless, even after acclimatization the performance of strenuous exercise, e g , marching, may lead to electrolyte and water depletion If the water is replaced without salt, cramps occur in muscles of limbs and abdominal wall They can be relieved by administration of NaCl tablets, or by assimilation of the electrolyte that is found naturally in most foods

Control of Sweat Secretion The sweat glands, which number over 2,500,000 in a man living in a temperate climate, are cholinergic although their innervation is by means of postganglionic fibers of the thoracolumbar division of the visceral motor system Sweating is controlled by mechanisms that are present in almost all levels of the nervous system For example, in the initial stages of muscular exercise sweating is apparently initiated by the discharge of impulses from the motor cortex, inasmuch as it occurs before there is any significant increase in heat load Later on in exercise a rise in hypothalamic temperature acts upon detectors at the hypothalamic level (Fig 9 111) Spinal centers exist for segmental control of sweating, this can be demonstrated in quadriplegic patients who sweat reflexly in parts of the body innervated below the level of the transverse lesion of the spinal cord

The few observations that have been made upon the secretion pressure of sweat indicate that it is high, 250 mm of Hg or more Sweat is therefore a true secretion and not simply a filtrate The rate of sweating may be really surprising, it may be as high as 1 6 liters an hour If it were all evaporated this would remove over 900 kcal of heat from the body in each hour

HEAT PRODUCTION

When the environmental temperature is in the range between 28° and 31° C, the basal heat production can be dissipated to the environment by radiation, convection, and insensible vaporization of water by an unclothed male subject If the environmental temperature is lowered below these levels, loss by radiation and convection become progressively greater, and the mean body temperature falls because the periphery becomes cooler At a level of about 23° C (sometimes called the "critical temperature" for a nude subject) shivering begins (Fig 9 112), and intensifies the rise in heat production that has occurred imperceptibly as the temperature fell below 28° C (Fig 9 110) This rise in metabolic rate occurs principally in skeletal muscles as a result of increased tension, even before shivering is initiated When shivering is intense the overall heat production may be as much as three times greater than the basal rate It is evident that this is a mechanism that is controlled by the somatic division of the nervous system, but that subserves an unconscious and automatic function in regulation of body temperature After the skeletal muscles are paralyzed by a drug such as curare, an animal loses the power to maintain a normal temperature in a cold environment Its ability to dissipate extra heat is not impaired, however, so that it can still resist high temperatures

CENTRAL MECHANISMS FOR TEMPERATURE REGULATION

Integration of the autonomic mechanisms that control heat loss and the somatic mechanisms that govern heat production, posture, and behavior, is accomplished in laboratory animals in the hypothalamus (In man the behavioral adjustments to thermal stress presumably involve higher levels of the nervous system) The significance of the hypothalamus can be illustrated by review of three types of evidence, as follows

a) Injury to the hypothalamus almost invariably leads to changes in body temperature If experimental lesions are placed in the rostral portion, the animal may exhibit a severe fever that may progress to death This fever is regarded as a release phenomenon analogous to decerebrate rigidity The rostral hypothalamus apparently contains an inhibitory mechanism that normally acts to suppress the mechanisms of heat production, and that also facilitates the stimulation of mechanisms of heat loss These particular results would follow the interruption of the loop by which information is returned to

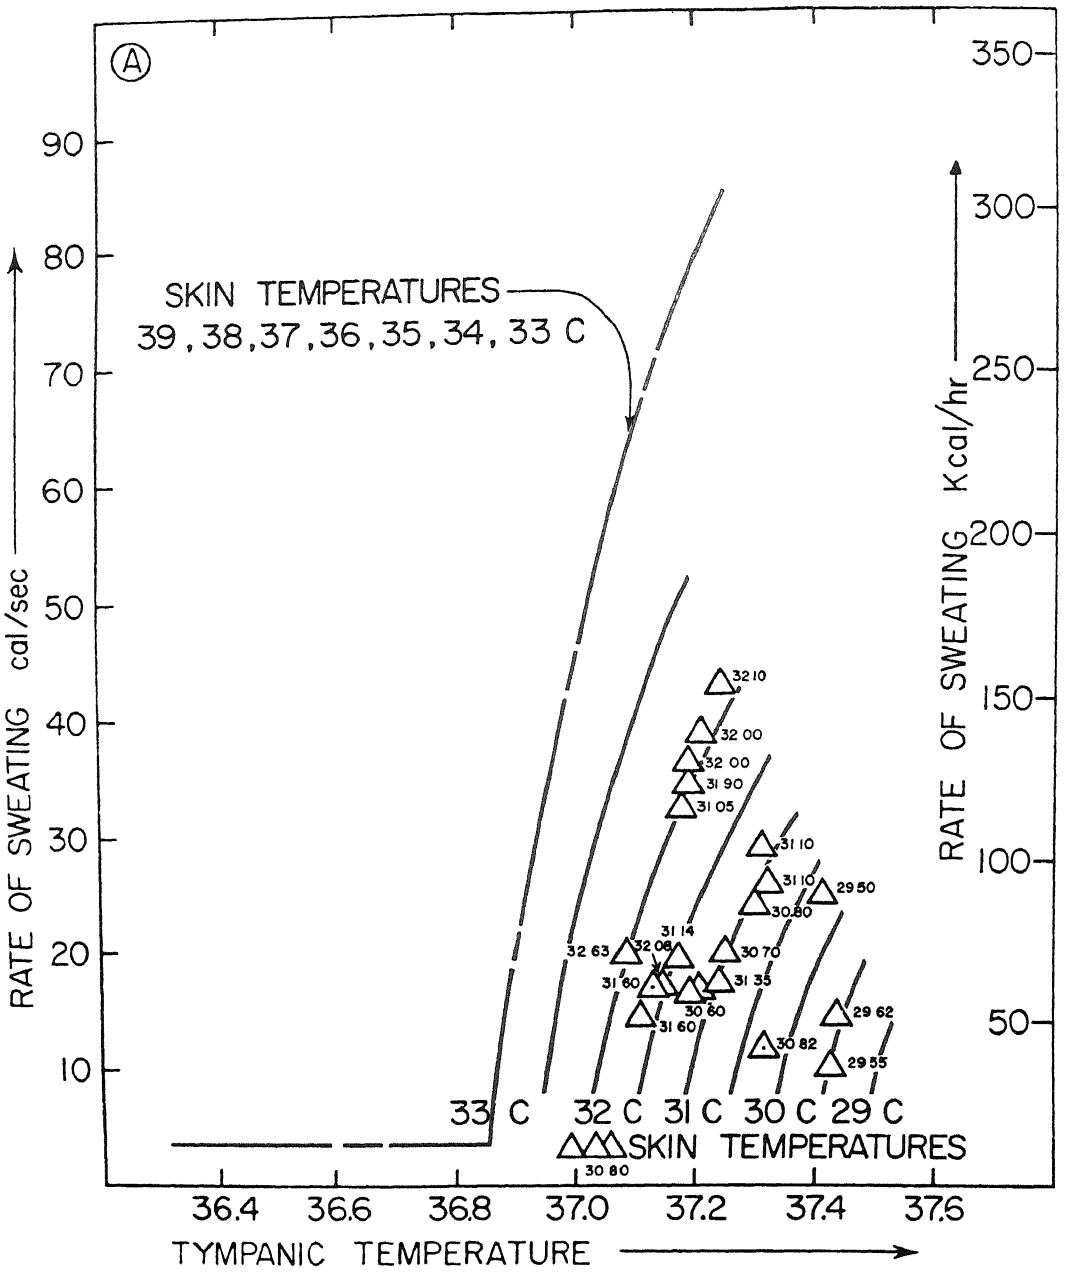

Fig 9 111 Rate of sweating of human subjects having differing central (*tympanic*) temperatures (*abscissa*), and a variety of skin temperatures (the family of *curves*) (Benzinger 1969)

the controller with a negative sign The usual therapy for fever of this type, particularly when it occurs in human patients after neurosurgical operations, is forced cooling by means of ice packs and cold water enemas A more specific therapy is administration of a barbiturate, Ranson and his associates (Beaton et al , 1943) discovered that such a drug selectively decreases the activity of fever-producing mechanisms and so permits body temperature to return to normal If the hypothalamic lesion is more caudal, and especially if it extends into the lateral hypothalamic areas, the patient or experimental animal will have a low

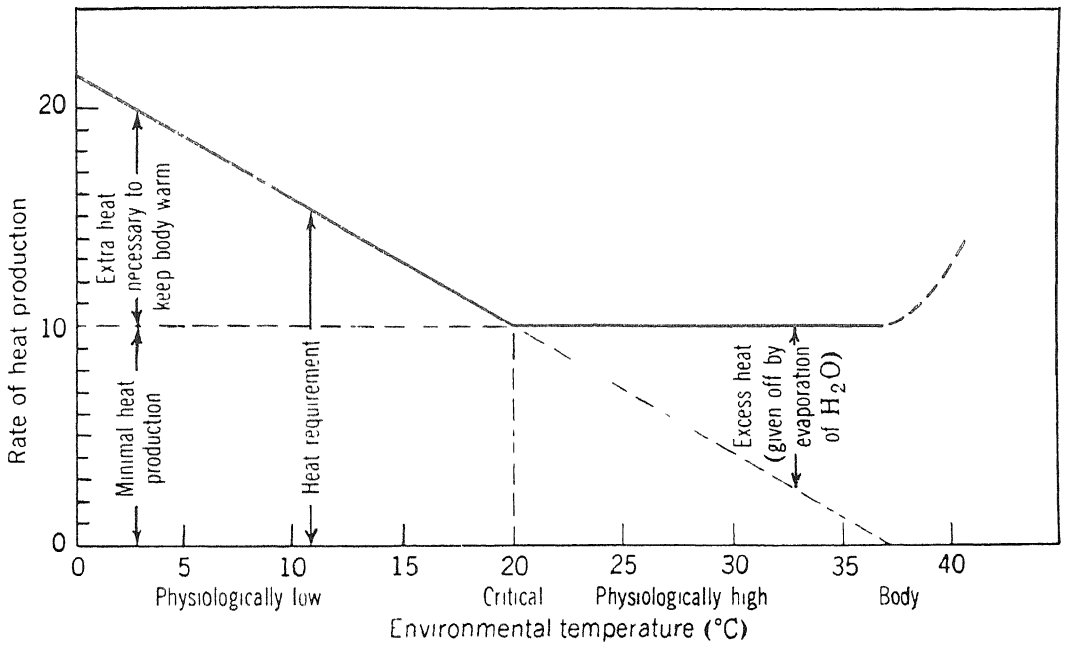

Fig 9 112 Diagram that illustrates the influence of environmental temperature upon metabolic rate At 20°C on this graph the subject can lose all metabolic heat without extra evaporation of water similarly body temperature can be maintained without shivering (Kleiber 1961)

temperature, particularly if the environment is cool This hypothermia can be corrected by artificial heating, but if it is not so treated it, too, may terminate fatally

b) The second type of evidence came from experiments such as those of Karplus and Kreidl (1910), and of Ranson (1936 to 1937) and his associates, who discovered that most of the reactions needed for temperature regulation can be brought into play by electrical stimulation of the hypothalamus The major exception to this statement is shivering, which cannot be induced by any conventional type of electrical stimulus It is a nonsynchronized but rhythmic phenomenon that requires a pattern of activation different from the varieties physiologists employ

c) The most explicit type of evidence comes from experiments in which the hypothalamus has been artificially warmed or cooled. If the temperature of the hypothalamus is changed by high frequency warming through electrodes, or by conduction via thermodes, an artificial feedback loop is created that is open, or independent of what is taking place in the control system Experiments of this variety were first done by Barbour (1912), who passed warmed or cooled water through fine tubes implanted in the brain of rabbits Later the technique was refined by Magoun et al (1939), who oriented electrodes using a stereotaxic method, for passage of a "diathermy" type of high frequency current through the hypothalamus The warming of a sensitive region that lies over the chiasm in cats, and ahead of it in monkeys, led to polypnea, panting, and sweating on foot pads Other investigators have extended the observations by use of implanted thermodes in unanesthetized animals, and have shown that this region is sensitive to cooling as well as heating It apparently serves as a thermostat for the rest of the body—as a thermal detector that originates a negative feedback (Benzinger, 1969) In a sense, it utilizes the rest of the body to stabilize its own temperature, cooling the body when it becomes warm, and retaining heat in the body and stimulating heat production when it is chilled (Fig 9 113) Investigators using microelectrodes have studied the function of single units in this region Although some neurons seem to be insensitive to temperature, and have been proposed as generators of a constant or set point signal, others

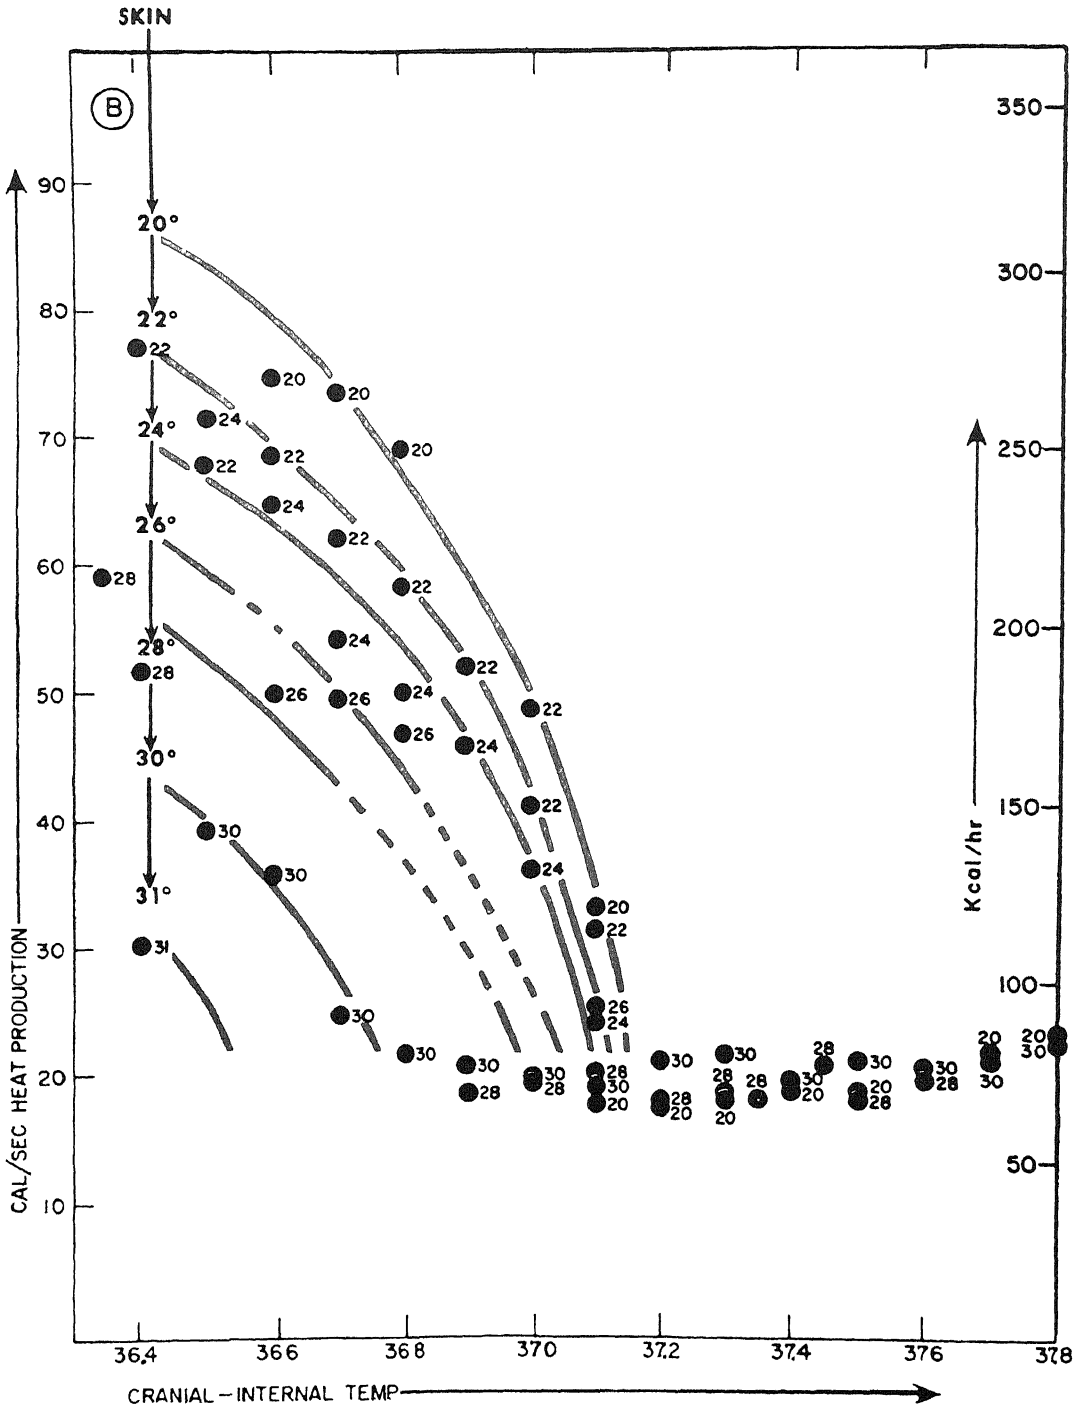

Fig 9 113 Relationship between central (*tympanic*) temperature and rate of heat production with skin temperature as another variable (family of *curves*) (Benzinger 1969)

respond to heating whereas still others are stimulated by cold (Figs 9 114 and 9 115)

In addition to this central detector and feedback loop, there is another similar loop that arises from thermal detectors in the skin (Figs 9 111 and 9 113) Its function is illustrated in Figure 9 116, where the response of an unanesthetized dog to heating of the hypothalamus is

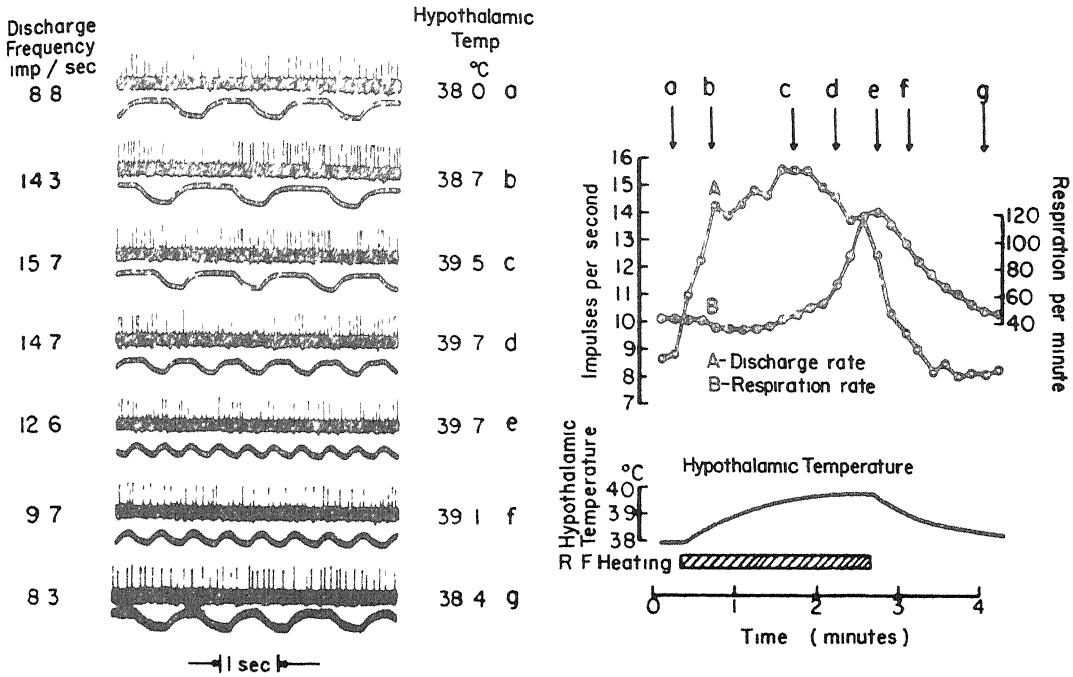

Fig 9 114 Action potentials recorded from single units in rostral hypothalamus during experiment in which the hypothalamus was warmed artificially through an implanted electrode The graphs indicate the course of the experiment and the frequency of firing of the unit (Nakayama et al 1961)

shown to depend upon ambient temperature Stolwijk and Hardy (1966) have devised a mathematical formula that combines these two kinds of signals According to their concept the body does not respond to a change in skin temperature when there is no central change, and likewise does not respond to central change in the absence of peripheral deviation They have concluded, therefore, that the central "integration" is some function of a mathematical product of the deviations in temperature in the two locations

The nature of the set point of this system has been considered by both Hardy (1965) and Hammel (1965), the latter suggested that the elevated temperature of exercise represents a change in set point that originates in neural adjustments inducing or accompanying the exercise A similar explanation may account for the elevated temperature of infectious fevers, but on a biochemical basis at the neuronal level (Eisenman, 1969). Toxins known as *pyrogens* are liberated by bacteria and can be isolated also from white blood cells (Wood, see Moore et al , 1970) In effect they stabilize the membrane of the central thermodetector neurons so that a higher temperature is required

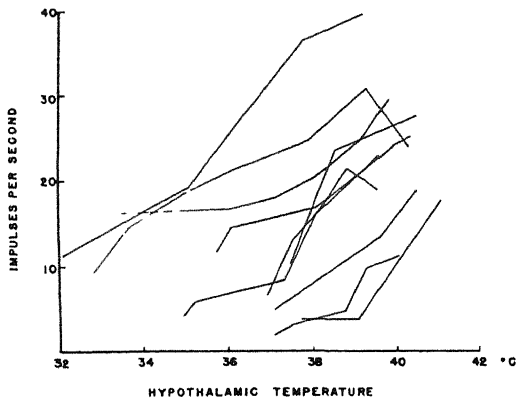

Fig 9 115 Frequency of firing of warm-sensitive units in rostral hypothalamus as a function of hypothalamic temperature (Hardy 1965)

to induce the negative feedback The possibility that the chemical intermediary of the action of pyrogens is the class of compounds known as prostaglandins has been suggested recently by Vane (1971). His suggestion is based upon the discovery that aspirin, a drug with pronounced antipyretic action, inhibits the synthesis of prostaglandins, and upon reports that prostaglandins injected directly into

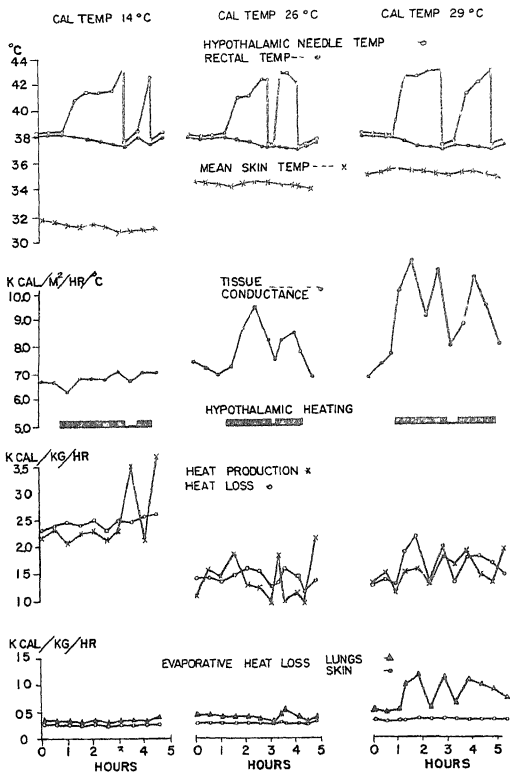

Fig 9 116 Records of experiments in which hypothalamus of a dog was warmed when the animal was exposed to three different environmental temperatures 14° C 26° C and 29° C Tissue conductance is a measure of vasodilatation in skin vessels (Fusco et al 1961)

the hypothalamus induce fever Prostaglandins are widely distributed compounds whose biological significance is not entirely clear, they are synthesized in the body from polyunsaturated fatty acids, and are believed to be related to the cyclic adenosine monophosphate system (Horton, 1969)

ENDOCRINE GLANDS IN THERMOREGULATION

The thyroid and adrenal glands play significant roles in the regulation of body temperature The calorigenic effects of the secretions of these glands are well known (sect 7, chap 4) Cannon (1932) observed that exposure to cold causes an increase in the rate of the denervated heart of a cat, as a result of epinephrine secretion This hormone exerts a calorigenic effect which is immediate and of short duration A less immediate and much more prolonged increase in heat production is brought about by stimulation of the thyroid gland Rats exposed over a period of 3 weeks to low temperatures (7° to 12° C) show thyroid hyperplasia and a rise in metabolic rate of as much as 16% Thyroidectomized rats, on the contrary, show little rise in metabolic rate under the same conditions Uotila (1939) found that this stimulation of the thyroid did not occur if the pituitary stalk had been previously sectioned He thus provided the earliest evidence that secretion of the thyrotrophic hormone by the anterior pituitary gland is under the control of hypothalamic mechanisms This control is now known to be exerted by way of thyrotrophin releasing factor (sect 7, chap 2)

Some years ago Ring (1942) demonstrated another interesting mechanism of protection against cold exposure when he found that thyroid hormone potentiates the calorigenic action of epinephrine This means that thyroidectomized animals not only are deficient in the action of thyroid hormone on metabolic rate, but also that the epinephrine they secrete in the cold has a reduced potency in elevating heat production even in a transient way

8 / HIGHER NEURAL FUNCTIONS

Sleep

Although sleep is known to everyone from personal experience, it has a special significance in neurophysiology Consider, for example, the results of a neurological examination performed upon a sleeping subject If the subject remains asleep throughout the examination, the examiner will note what appear to be catastrophic deficiencies of central neural function—as contrasted to the waking state These include loss of muscle tone and changes in both cutaneous and deep reflexes, elevated threshold for all types of sensory stimulation, almost complete dissociation from the environment, visceral changes including fall in metabolic rate, lowering of central body temperature, perhaps an elevation of skin temperature, and a lowering of blood pressure and heart rate, and a respiratory pattern different from that of the waking state to a degree that in infants may include periodic breathing This constellation of neurological signs would be consistent with some profound neurological injury, were it not that they disappear upon waking

The transition from sleep to waking, and the preservation of the waking state are functions of a mechanism that lies in the hypothalamus and the tegmentum of mesencephalon and pons It can be brought into activity by sensory stimulation, as for example an alarm clock It is believed also to contain, however, circuits of neurons that give it what appears to be an inertia (in the physical sense)—a momentum so that it keeps an individual awake in the intervals between arrival of particular sensory stimuli It may actually include also neurons that can generate signals, as described in chapter 1

What serves as a switching mechanism to convert the central nervous system from sleep to waking or vice versa is not known

EEG OF SLEEP

The principal tool for study of these phenomena is the electroencephalogram (EEG), described in chapter 6, p 9–116, which exhibits different patterns in the waking and sleeping states (Fig 9 117) It is true that some of the patterns seen during sleep occur also in waking, and vice versa (Jouvet, 1967) Nevertheless, the correlation between the EEG record and sleep is quite good, for studies on experimental animals and infants there is no equally useful technique for analyzing sleep

A subject who is awake and alert to his environment shows in his EEG from all cortical areas a random pattern of fast waves of low voltage that is believed to arise from lack of synchronization of the neurons responsible for the electrical activity in the area under the electrode If the subject closes his eyes, the pattern changes and begins to show the α rhythm (Berger, 1929) If the subject then becomes drowsy the α waves become less prominent, and larger, slower waves begin to appear in bursts lasting a few seconds With the onset of light sleep the α waves are gone, the record shows mainly low voltage fast waves again, and sleep "spindles" are seen (Fig 9 118) These latter are short bursts of waves having a frequency of 14 to 16/sec , with a gradual increase and then a decrease in voltage so that the overall profile of the complex is something like an elongated, slim American football During deep sleep these spindles likewise become less prominent and may even disappear, the record is then dominated by slow waves of relatively high voltage that may have been noted first during the stage of light sleep These waves mark the condition known as "slow sleep," more correctly, sleep characterized by synchronized cortical activity When wakening takes place, the pattern returns very quickly to the asynchronized, fast, low voltage activity and the process of *activation* of the EEG is said to have occurred

During the stage of sleep with slow waves (synchronized cortical electrical activity) there may occur every now and again another kind of record that ressembles the activated pattern Waves are momentarily fast and of low voltage (Derbyshire et al , 1936, Rheinberger

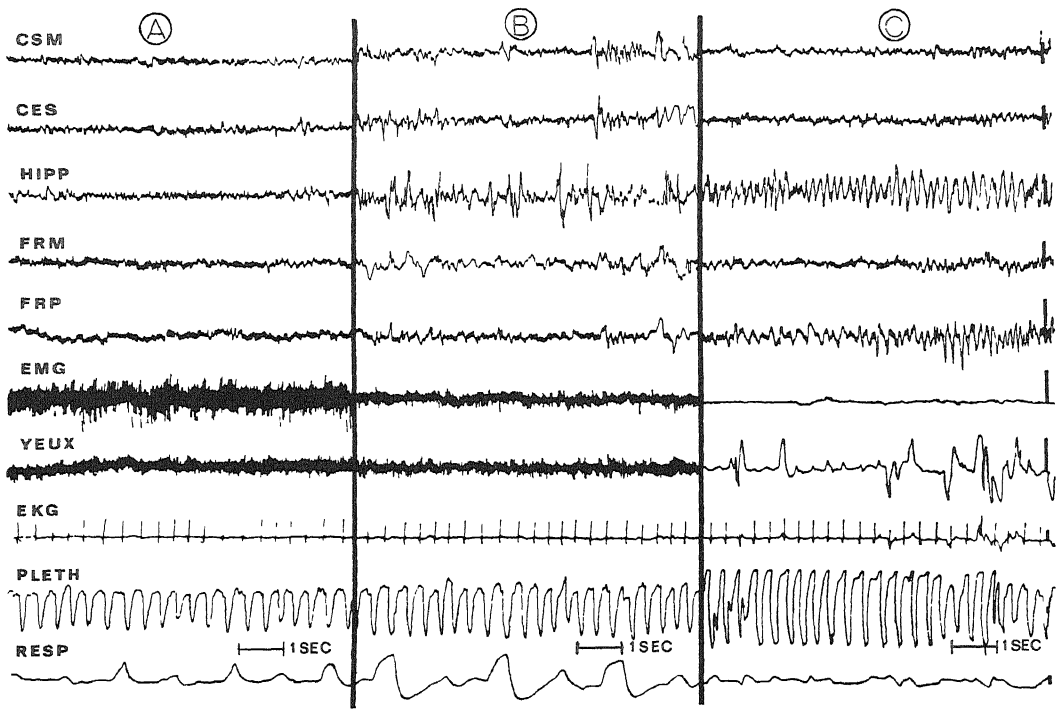

Fig 9 117 Electrical recordings that show differences in (*A*) waking state (*B*) slow wave sleep and (*C*) paradoxical sleep (Jouvet 1967)

and Jasper, 1937) Their onset is accompanied by neurological signs that the subject is in a deeper condition of sleep, contrary to what the EEG asynchronization suggests There is complete relaxation of antigravity muscles, disappearance of stretch reflexes, rapid movements of the eyes (abbreviated as REM for "rapid eye movements"), together with movements that may include twitching, jerking, or even mild convulsions (Fig 9 117) In laboratory or domestic animals one may see moving of the vibrissae, extremities and tail Everyone who has observed the sleeping state of a pet cat or dog has noticed this type of movement The loss of tone in antigravity muscles and the absence of stretch reflexes serve to distinguish this condition from any tendency towards wakening Furthermore, the threshold for arousal is higher than when the EEG shows the slower type of waves This condition, known as "fast sleep"—sleep with fast waves—is also called *paradoxical sleep* because of the inconsistency between the neurological condition and the EEG wave forms It is one of the deepest stages of sleep (Jouvet, 1967)

SLEEP WITH SLOW WAVES

In most of the experimental literature devoted to the subject of sleep, the condition studied was the one characterized by large, slow waves in the EEG, the apparently synchronized type of electrical activity It has been analyzed in experimental animals after surgical transection of the neuroaxis, as well as with the aid of the stereotaxic instrument for placement of lesions, for stimulation or for recording Modern work on this problem began just before World War II with a publication by the Belgian neurologist, Frederic Bremer (1936) He transected the brainstem of cats in the midcollicular region of the mesencephalon, thereby creating what he referred to as a *cerveau isole* preparation (with "isolated mind") The cerebral cortex of such an animal appears to be continually asleep as judged by the EEG pattern, and it cannot be activated by at-

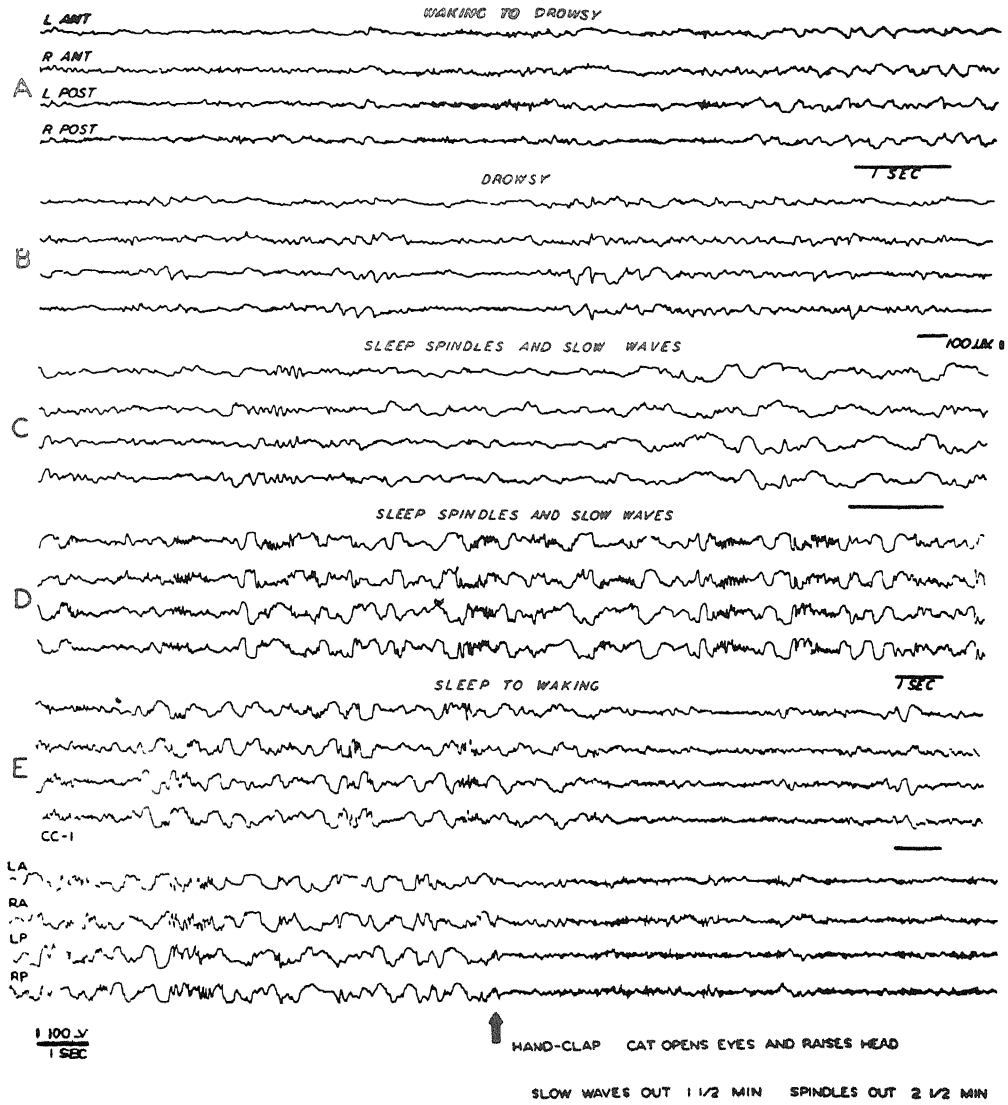

Fig 9 118 *A–E.* Electrocorticogram of cat as it passed from waking to sleep and then awakened again *Bottom* Cat awakened by hand-clap (Magoun 1952)

tempts to arouse the animal On the other hand, if the plane of transection is at the lower border of the medulla oblongata (*encephale isolé*, "isolated brain"), the EEG may show the waking pattern, alternating with periods in which the pattern is characteristic of sleep Moreover, the sleep pattern can be converted to the waking pattern by sensory stimulation via cranial nerves. (One should note that the preparation with *encephale isolé* requires artificial respiration because the medullary respiratory centers are cut off from respiratory motor mechanisms in cervical and thoracic cord)

Bremer's interpretation of his findings was that the sleeping state of the *cerveau isolé* preparation was the result of removal of sensory input as a result of transection of ascending pathways between brainstem and cortex In the preparation with the lower level of section, by contrast, the ascending pathways from sensory portions of cranial nerves remain intact and capable of stimulating higher levels including thalamus and cortex Later experi-

ments showed, however, that mechanisms other than the sensory systems are necessary for preservation of the waking state

Reticular Activating Mechanism. This latter, alternate interpretation came from experiments in which Lindsley and his associates (1950) performed stereotaxic operations that only partially transected the brainstem Certain of the lesions were placed laterally so that they interrupted the specific or lemniscal sensory pathways on each side Others were placed medially in the central portion of the reticular formation on both sides of the midline (Fig 9 119) In animals with the lateral lesions a normal transition from sleeping to waking state occurred as judged both from the behavior of the animal and from the EEG But in animals with medial lesions the sleeping state was prolonged as in Bremer's *cerveau isolé* preparation, with one significant difference Because the main sensory pathways were intact following the medial lesions, sensory stimulation would activate the cortical electrical pattern momentarily Then when the stimulation was ended the cortex lapsed into a sleeping pattern (Fig 9 120) These observations confirmed the ability of sensory input to alert the cortex as Bremer had inferred, while they showed also that the maintenance of an alert state between stimulations depends upon projections from the medial reticular formation to higher levels of the brain

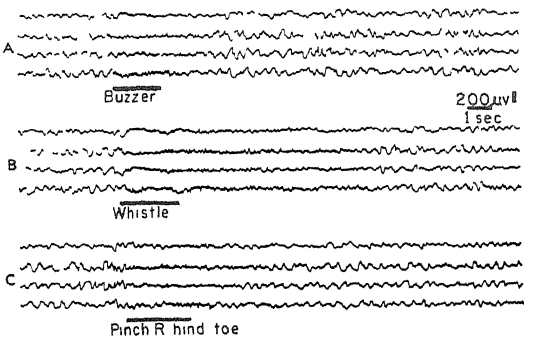

Fig 9 120 EEG of cat with lesion shown in Figure 9 119 Record shows persistent sleep pattern with brief transition to waking pattern during and just after stimulation by sound or pain Four different cortical regions show similar wave forms (Lindsley et al , 1950)

Further data on this question have been obtained by the technique of stimulation Mo-

ruzzi and Magoun (1949) found that electrical stimulation of the medial reticular formation transforms a high voltage, slow wave EEG into the low voltage, fast wave or activated pattern Because it has this property of alerting the cerebral cortex this function of the reticular formation is ascribed to the *ascending activating system* Its influence is transmitted via multisynaptic pathways via the nonspecific thalamic nuclei, and thence to the cerebral cortex (Chap 2, p 9-40) The portions of the reticular formation that are concerned with activation of the cortical EEG are, to some degree, under the control of the cortex Segundo (1956) and his colleagues have shown that electrical stimulation of certain cortical regions will produce an EEG desynchronization which appears to be identical with the desynchronization observed by Moruzzi and Magoun (1949) after electrical stimulation of the reticular formation In a feedback loop the ascending activating system is stimulating cortical alertness, but the cortex is also projecting back to brainstem to modify the output of the activating mechanism The presence of this feedback pathway was demonstrated by Jasper et al (1952), and by French et al (1955), who recorded evoked potentials from the reticular formation following stimulation of a variety of areas in the cerebral cortex

The fact that the lateral hypothalamus is anatomically and functionally continuous with the reticular formation was first suggested by studies on sleep A number of conditions that occur clinically are typified by somnolence, prolonged sleep, or even coma (chap 9, p 9-177), in patients with lesions in the hypothalamus or mesencephalon The lesions may be caused by an infection as in "sleeping sickness" (von Economo, 1929), or may be a result of pressure from a tumor, or of hemorrhage or occlusion of a blood vessel Ranson (1936 to 1937) and his associates found that injury to the caudal part of the lateral hypothalamus produces in monkeys a somnolence that appears to be identical with the clinical condition. Stimulation of this region through chronically implanted electrodes causes animals to become alert and active

The current hypothesis, therefore, is that the waking state is initiated and maintained by projections from the reticular formation (including lateral hypothalamus) via nonspecific pathways through thalamus to cerebral cortex (Fig. 9 121) The next question is, what turns

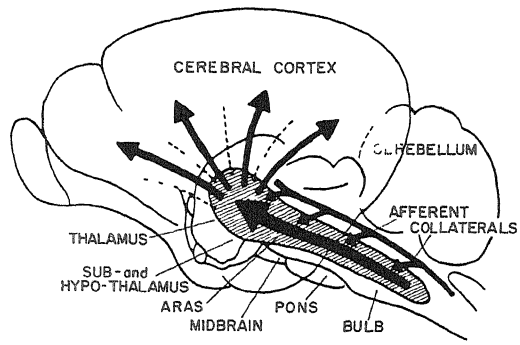

Fig 9 121 Outline of the brain of the cat showing general location of the activating mechanism in the tegmentum of the brainstem and its relation to principal afferent systems and projections via thalamus to cerebral cortex Starzl et al cited from Magoun 1952

on the reticular activating system? This question, too, has been investigated by authors who have stimulated the several parts of the brainstem Pioneer work was done by the Swiss neurophysiologist, W R Hess, who invented a technique for implanting electrodes in anesthetized cats in a manner that permitted stimulation later after the animal had recovered from the operation (Fig 9 6, p 9-9) In the course of experiments begun in 1925 and summarized later (Hess, 1954), he discovered that the application of a particular type of stimulation to the thalamus lateral to the ventral portion of the massa intermedia would produce sleep From these results he concluded that the brain contains a mechanism that induces sleep in an active sense A series of papers by Akert et al (1952, see also R Hess, Jr, et al, 1953) has essentially confirmed the earlier observations, and extended them by showing the expected correlations between the state of the animal and the EEG Their data imply that the sleep-waking mechanism, like other components of the central nervous system as described in preceding pages, is a dual system It may have a portion that turns on the waking state, and another that "turns off" waking and so induces sleep If so, it fits into the pattern of reciprocal interaction of alternating inhibition and facilitation that can be identified at all levels of the neuroaxis

Hypothalamic Suppressor Mechanism Evidence as to the existence and location of this second component of the control system has come also from experiments in which the opposite of somnolence has been observed after operations upon the base of the brain

Although Hetherington and Ranson (1942) did not report any observations upon sleep as such, they did observe a condition of extreme, prolonged, and "frantic" hyperactivity in rats just after operations upon the tuberal hypothalamus Later these rats became almost completely inactive With lesions placed more rostrally in the suprachiasmatic or preoptic region, however, Nauta (1946) observed both hyperactivity and lack of sleep McGinty and Sterman (1968) have recently described similar changes in cats with large, bilateral suprachiasmatic lesions, and have correlated the behavior of the animals with their EEG patterns The largest lesions abolished sleep, smaller ones significantly decreased the duration of both the slow-wave and paradoxical stages of sleep Taken together these data suggest that, if there is a dual mechanism for the sleeping-waking control, one part lies ahead of the other The caudal hypothalamus and reticular formation seem to contain the activating component, whereas the rostral hypothalamus and preoptic region include the suppressor The relation of these results to those of Hess and others as presented in the preceding paragraph, however, is not yet clear

PARADOXICAL SLEEP

As noted above, paradoxical sleep or REM sleep is characterized by low voltage fast EEG, profound atonia of the somatic musculature, and rapid conjugate eye movements In addition, recordings from deep structures and cortex show a θ (4 to 7 cycles/sec) pattern in the hippocampus and intermittent bursts of activity in the pons, the lateral geniculate body, and visual cortex Jouvet (1967) has classified the phenomena of paradoxical sleep into two categories, tonic and phasic Tonic phenomena include the EEG, hippocampal θ rhythms, and muscular atonia Phasic phenomena include the rapid eye movements, the bursts of activity in the pons-geniculate-cortical complex, and occasional muscle twitches In a series of studies in which lesions were placed in a variety of regions, Jouvet has determined that the structures apparently responsible for the phasic components of paradoxical sleep are the rostral part of the nucleus reticularis pontis candalis and the caudal part of the nucleus reticularis pontis oralis Stimulation of these regions in the tegmentum of the pons during normal sleep produces paradoxical sleep

More recently Jouvet has also found that bilateral lesions in the region of the locus caeruleus will suppress or abolish the tonic component of paradoxical sleep without affecting the phasic component Animals in which the tonic component has been abolished by such lesions show considerably increased muscle twitching during phasic paradoxical sleep

HUMORAL MECHANISMS OF SLEEP AND WAKEFULNESS

Legendre and Pieron (1910) suggested that an unknown substance, which they called hypnotoxin, found in the cerebrospinal fluid (CSF) is involved in producing sleep They observed that CSF removed from fatigued animals and injected intracisternally into normal, rested animals tended to induce sleep Schnedorf and Ivy (1939) replicated these experiments with additional controls Dogs that received CSF from fatigued dogs apparently went into a deep sleep Control dogs, which received CSF from rested dogs, or injections of their own CSF, however, also showed some depression but to a lesser extent Many other authors have attempted similar experiments Their results have been summarized by Jouvet (1967) in the suggestion that serotonin is the neural transmitter that induces sleep

The existence of an activating substance was suggested by Purpura (1956) He connected each femoral artery of a cat to a femoral vein of a second cat and vice versa to obtain intermixing of the total blood volume Stimulation of the medial bulbar reticular formation produced immediate cortical activation in the stimulated cat After about 60 sec an activation pattern could be seen in the electrocorticogram of the recipient cat Unfortunately, Purpura was unable, on the basis of available evidence, to advance an hypothesis concerning the identity of the circulating activator substance

More recently, Monnier and Hosli (1965) have reported that dialysate from venous blood of sleeping or active donor rabbits will produce sleep or alert behavior, respectively, when injected into the circulation of recipient rabbits

The more recent studies of paradoxical sleep have suggested humoral mechanisms controlling this form of sleep also Among the more ingenious studies in this area was one by Jouvet (1967) and his colleagues who devised a method of differentially depriving animals of

paradoxical sleep but not slow sleep Jouvet placed cats on a brick in a shallow pool of water for periods of days The animals maintained sufficient muscle tone during slow sleep to be able to keep from falling into the water During paradoxical sleep, muscle tone decreased to the point that the animals fell into the water, waking up Animals deprived in this fashion of paradoxical sleep seemed to build up a need for paradoxical sleep, for when allowed to sleep normally the percentage of sleeping time devoted to paradoxical sleep was far greater than normal This build-up of a need for paradoxical sleep is attributed to the accumulation of an unidentified substance during paradoxical sleep deprivation Related studies in which humans were deprived of paradoxical sleep, by being awakened whenever EEG and eye movement records indicated paradoxical sleep, also show the same build-up of need for paradoxical sleep This accumulation can be suppressed by monoamine oxidase inhibitors For example, administration of Nialamide to animals deprived of paradoxical sleep will prevent the subsequent appearance of paradoxical sleep 5-Hydroxytryptophan will also suppress paradoxical sleep γ-Butyrolactone in doses of approximately 50 mg /kg will produce paradoxical sleep and large doses of Reserpine will differentially produce the phasic phenomena of paradoxical sleep On the basis of such evidence, Jouvet (1967) has suggested that the substance accumulating during paradoxical sleep deprivation may be an amine, probably norepinephrine

SIGNIFICANCE OF SLEEP

Every thoughtful person has speculated as to the function of sleep Yet almost nothing is known of it scientifically It is clear that in the absence of sleep the more subtle functions of the nervous system are affected first, with changes in mood, motivation, and attention (Wilkinson, 1969) With more prolonged sleep deprivation even the subcortical, more nearly automatic functions of the brain suffer, and symptoms such as tremors, nystagmus, ptosis, and dysarthria occur (Sassin, 1970) As Hobson (1969) has pointed out, there are certain forms of illness that are most likely to occur when the patient is asleep, they include nocturnal angina, asthma, and emphysematous anoxia

One may suppose that neurons are not capable of continuous, repetitive discharge, although what happens to limit this capacity is unknown It might be some limitation of energy transduction, or it might be the accumulation of ions during activity that must be extruded during recovery, or it might be some as yet immeasurable change in the properties of one or more of the neuron's membrane systems Those cells that are active in both waking and sleeping states, such as the respiratory system, are not continuously active, rather, they have their own cycles of activity and rest, such as the cycle that includes inspiration-expiration-inspiration, etc Most of the neural control systems exhibit some form of rhythmicity like this, or at least some alteration in the level of their discharge Not so the activating mechanism Unless it has some mechanism for operating on a basis of "taking turns," it seems to be discharging more or less continuously so long as the individual is awake It appears that neurons are not constituted so as to permit this kind of continuous activity indefinitely

Emotion

How we "feel" is so important to everyone, and disorders of emotional state are so prevalent and troublesome, that any possible understanding is desirable both for the insight it may provide into human behavior, and for its practical value in clinical medicine In the same manner in which one can distinguish between movement and a desire to move, it is possible to separate emotional expression from emotional experience Emotional expression, like a movement of the body can be studied in laboratory animals, in infants incapable of speech, or in other circumstances where verbal or written communication is not possible To attempt to analyze volition or the experience of an emotion, by contrast, requires either that the observer himself be the subject of the investigation, or that the subject be able to report to the observer just what he believes to have taken place There are, therefore, two almost completely separate kinds of literature on the neurophysiology of emotion One is concerned with animal behavior following operations upon the nervous system, the neurohistology in such reports tends to be precise and even elegant, but the nature of the emotional experience is uncertain because it can be inferred only from an anthromorphic point of view On the other hand, reports based upon the experience of human patients with lesions of the central nervous system may be highly

informative as to the kinds of emotion the individuals have undergone, but often are deficient in precise neurological localization, because such lesions usually are not localized sharply enough to permit the assignment of any one function to any specific structure

EXPERIENCE VS EXPRESSION

There is no certain knowledge as to mechanisms that create *awareness* of the state of emotional tone This problem is akin to the question of how does the individual finally become aware of any type of sensory or motor experience Perhaps the cerebral cortex contains a scanning mechanism that at some frequency surveys and registers the overall patterns of activity in all regions If so, then what scans the scanner?

The *expression* of emotional states, on the other hand, can be attributed fairly reliably to mechanisms that already have been mentioned, including *a*) those cortical regions from which autonomic responses can be evoked upon stimulation, *b*) the intermediate or transitional portion of the neuroaxis known as the limbic system (see later), and *c*) the hypothalamus and its projections to brainstem and spinal cord Bard (1928) suggested that these portions of the brain, but especially the hypothalamus, are responsible for "integration" of the somatic and visceral phenomena that characterize behavior that accompanies emotion The functions of these neural mechanisms have been studied in different species of laboratory animals, with reference to several typical emotional states (see Pribram, 1969, Black, 1970) The one that is perhaps the best understood is *rage*, mainly because early investigators found that it can be evoked easily under laboratory conditions, as reviewed in the following paragraphs Other motions that have been studied include *placidity*, what appears to be *pleasure* (as judged by purring of cats, and other similar behavior), and emotions presumably associated with behavior patterns of *reproduction* The list is scarcely a satisfactory one, when it is contrasted with the range and variety of human emotional tone

SHAM RAGE

It was first demonstrated by Goltz and Ewald, (1896) that the reactions which usually accompany displeasure and anger are more readily evoked in an animal deprived of its cerebral cortex (decorticated) than in the normal animal In Goltz's classical experiment the hemispheres and a large part of the thalamus were removed from a dog The disposition of the animal was greatly altered by the operation, it being very readily aroused to anger Barking, growling, baring the teeth, or snapping occurred upon the least provocation Cannon and Britton (1925) produced a similar state in cats by removal of the cortex, the decortication being performed by means of a pointed stilet inserted through the orbital cavities Immediately following recovery from the anesthetic the animals showed the following remarkable phenomena which these observers termed *sham rage*—lashing of the tail, erection of the hairs, protrusion of the claws, dilatation of the pupils, sweating, struggling and biting, greatly increased rate of respiration, and a rise in blood pressure Most of these manifestations will be recognized as being of sympathetic origin In many instances the picture was a combination of fear and anger Liberation of epinephrine, as indicated by an increase in the rate of the denervated heart, also occurred The mildest stimulus such as jarring the table or lightly touching the animal was sufficient to evoke a paroxysm of rage The condition was designated as "sham" or as "quasi," because these investigators believed that true rage cannot be experienced unless higher levels of the cerebral cortical mechanisms are involved

In decortication experiments Bard (1928) found that the posterior and ventral portions of the diencephalon are responsible for the development of sham rage Typical behavior occurred after decortication and section through the hypothalamus at about the middle of the tuber cinereum Rage also was noted after an operation that removed the basal ganglia and the dorsal half of the diencephalon, i e , the thalamus, but left the hypothalamus connected with the midbrain The condition failed to appear if the section separated the caudal part of the hypothalamus from the brainstem as a high level decerebration

HYPOTHALAMIC RESTRAINING MECHANISM

Another variety of rage was discovered by Wheatley (1944) when he was studying hypothalamic hyperphagia in cats He noted that bilateral lesions in the ventromedial region of

the hypothalamus not only lead to overeating and obesity, but also to a behavior pattern in which the animals are " extremely, chronically and incurably savage in behavior and expression" (Ingram, 1952, p 401) These animals are so vicious that it is all but impossible for laboratory personnel to handle them Apparently they cannot be tamed once the lesions have been made Moreover, the change in behavior from the friendliness of a pussycat to this malevolent wildness seems to occur instantaneously because it is evident immediately after recovery from the anesthesia of the operation Although it is a hypothalamic injury that leads to this syndrome, this is not sham rage and seems to have little in common with the quasi-emotional state observed by Goltz, by Cannon, and by Bard and their associates There is nothing that can be called pseudo, sham, or quasi about the performance of a cat with ventromedial lesions The animal seems to possess full cortical function, both sensory and motor, and gives every evidence of experiencing the emotion it expresses Its rage is perfectly directed at whomever disturbs it, whereas sham rage cannot be directed and is therefore relatively innocuous Compared to the extensive ablations that lead to sham rage, the lesions that are effective in the ventromedial region are tiny Thus far, the syndrome is known to appear only in cats, rats with similar lesions do not show similar behavior to the same degree, and perhaps not at all, whereas macaque monkeys with ventromedial lesions are reported to be obviously more tame and friendly the morning following the operation (Hamilton, C L, personal communication)

CORTICAL INHIBITORY MECHANISMS

Both of these types of rage seem to be analogous to decerebrate rigidity in that they are caused by over activity of mechanisms that the surgical operation has released from an inhibition or restraint usually provided by the regions that were taken away In Wheatley's experiments the ventromedial nuclei of the hypothalamus seemed to be the origin of the restraint, or perhaps a vital part of the pathway by which it is exercised when the brain is intact. In the case of the sham rage, however, the inhibition seems to come from certain critical regions of the cerebral cortex. Thus, Bard and Mountcastle (1948) have shown in cats that the restraining influence is exerted in certain parts of the rhinencephalon (the cortex of the pyriform lobe, amygdaloid nucleus and hippocampal formation) and an area of cortex lying ventral to the cingular sulcus in front of and below the rostrum of the corpus callosum The cortex of this cingulate gyrus and the hippocampus are portions of the limbic system, a transitional zone between the rhinencephalon and the neocortex Following operations that removed the neocortex alone, leaving the rhinencephalon and transitional cortex uninjured, the cats showed a completely different kind of behavior They were extraordinarily placid, responses that seemed to express pleasure were predominant and often exaggerated Procedures that in a normal animal provoke struggling, clawing or biting, or an attempt to escape, in these cats evoked no sign of anger or even of displeasure The animals responded to mild nociceptive stimulation by purring. Subsequent removal of those parts of the limbic system mentioned above transformed these animals from a state of placidity into one where upon the slightest provocation they exhibited all the signs of rage They were in this respect, therefore, similar to the cats of Wheatley's experiments

It is apparent from these experiments that the cortex and other regions of the brain exert a restraining influence upon those mechanisms of caudal hypothalamus and brainstem that govern the expression of displeasure, resentment, and anger, at least in cats and dogs

Similar operations performed upon monkeys have given results that are in some respects different, and that are even more interesting than the experiments in which cats and dogs were used Kluver and Bucy (1939) reported that bilateral extirpation of the temporal lobes in monkeys, including both the neocortex and the rhinencephalon on the medial surface of the lobes, gave rise to a group of symptoms that has become known as the Kluver-Bucy syndrome It includes the following *1) Visual agnosia.* These animals seem to have lost the ability to recognize and to detect the meaning of objects on the basis of visual criteria alone There also seems to be a similar agnosia in the auditory and tactile fields *2) Oral tendencies* There is a very strong tendency to examine all objects with the mouth *3) "Hypermetamorphosis."* There is a marked tendency to take notice of and to attend to every visual stimulus *4) Tameness* These animals seem to

have lost their sense of fear, and there is a marked diminution in their emotional responses 5) *Hypersexuality* There is a striking increase in various sexual activities and in their diversity This change does not occur until several weeks after the operation Females may show a complete lack of maternal behavior 6) *Changes in dietary habits* Monkeys do not ordinarily eat meat but after the removal of both temporal lobes they do so without hesitation There is also an increase in the amount of food consumed In a few cases some of these symptoms have been observed also in human beings following bilateral temporal lobectomy

In later experiments by other authors it was possible to attribute some of these changes to specific structures within the temporal lobe For example, removal of the amygdala and overlying pyriform cortex is said to produce placidity (Schreiner and Kling, 1953) The hypersexuality has been attributed to lesions of the pyriform cortex without injury to the amygdala (Green et al , 1957) And it has been suggested that the psychic blindness may be the result of removal of the temporal neocortex, or perhaps of connections between the visual system and the posterior regions of the limbic system

LIMBIC SYSTEM

Fibers in the olfactory tracts terminate in the medial and lateral olfactory striae of the mesial and orbital cortex, from which there arise projections that are so variegated and that extend to so many other regions of the brain that the whole complex has been classified as a distinct portion of the nervous system, the *rhinencephalon* or "nose brain " In 1933 the American neuroanatomist, C Judson Herrick, surveyed the possible functions of the parts of the cerebral cortex belonging to this olfactory brain, and noted that they are "bound up with" other neural systems including those for feeding, nutrition, and reproduction Furthermore, the olfactory sense gives warning of danger, and guides an animal to a mate, to food, and "other desirables " He also observed that these portions of the brain are remarkably constant in their organization from lowest to highest of the vertebrates From these and other considerations he suggested that the olfactory system has two functions, *a*) adjustments in other systems so as to secure external orientation of the body, and *b*) an action " upon the internal apparatus of the general bodily attitude, disposition, and affective tone " (p 14)

This latter inference of Herrick was made more specific in 1937 by Papez in the form of a proposal that the principal functions of most of the supposed components of the rhinencephalon are not directly concerned with olfaction, but rather with emotional experience To reach this conclusion Papez drew upon the two types of evidence mentioned above He reviewed what was known of the location of lesions that in human patients were associated with emotional disorders, and he summarized also the results of Cannon, Bard, Ranson, and other authors (see above) whose work had disclosed the role of the hypothalamus in the expression of emotion such as rage, and in other autonomic patterns From these two lines of research Papez decided that the anterior nuclei of the thalamus, the cingulate gyrus, the hippocampus, and the interconnections of these regions constitute " a harmonious mechanism which may elaborate the functions of central emotion" He further suggested that the expression of the emotion is brought about via projections from these structures to the hypothalamic mechanisms other authors had described (Fig 9 122) In 1952 these portions of the brain were given the name, *limbic system* by MacLean (1967), because Broca had used that word to designate the portion of the

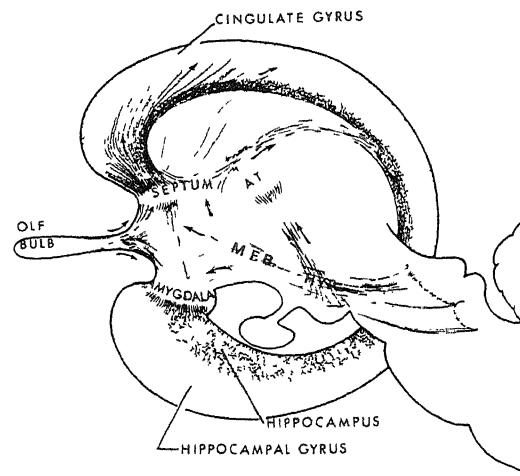

Fig 9 122 Principal interconnections of rhinencephalon with diencephalon and limbic cortex *AT* anterior nucleus of thalamus, *HYP* hypothalamus *MFB* medial forebrain bundle of fibers, they run through the lateral hypothalamus Cited from MacLean 1967

cortex that has the character of a "border" as it surrounds the brainstem The limbic cortex is intermediate in position between the portions of the brain that are common to even the most primitive vertebrates, and the neocortex that characterizes primates and man MacLean pointed out that in the cortex the levels of function cannot be represented by horizontal or coronal planes of section, but rather are arranged concentrically, with the most primitive in and adjacent to the brainstem, and the most advanced in the most superficial location (Fig 9 123) In the limbic system the principal cortical structures are the cingulate and hippocampal gyri, and the hippocampus (Fig 9 124) Subcortical portions include the amygdala (also classified as one of the basal ganglia) and the region known as the septum This latter is found on each side near the midline, a part of the telencephalon that is virtually continuous with the dorsal and rostral hypothalamus Stimulation of the cortex belonging to this system in anesthetized animals evokes autonomic responses such as changes in blood pressure, heart rate, gastrointestinal motility and secretion, as well as in pulmonary ventilation (Kaada et al , 1949) In animals not anesthetized this stimulation results in " pleasure, grooming and sexual reactions seen in courtship behavior" (MacLean, 1970, p 134) The connections of these structures with other parts of the brain have been followed histologically, and also by means of the technique of evoked potentials

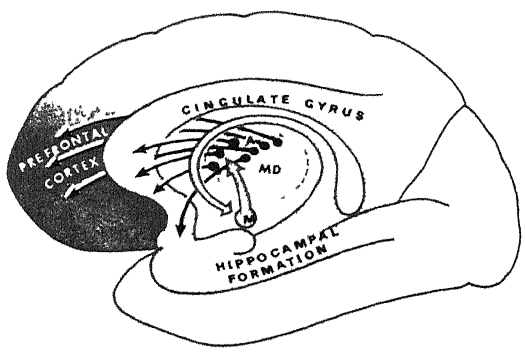

Fig 9 124 Relationships of thalamus with cerebral cortex, including cingulate gyrus and prefrontal cortex *A*, anterior nucleus of thalamus, *MD*, dorsomedial nucleus of thalamus, *M* mammillary body (MacLean, 1967)

Human patients with lesions in these areas are said to undergo a form of epilepsy (psychomotor) where the symptoms are autonomic discharge and emotional experience, stimulation during neurosurgical operations by way of electrodes applied to these structures evokes responses comparable to the psychomotor epilepsy (Penfield and Jasper, 1954) In a few persons recordings have been made, and stimulation has been applied, through implanted electrodes, while they are living a more or less conventional life as hospital patients The data so obtained are in general agreement with results obtained from experimental animals For example, "spontaneous" bursts of anger were evoked by stimulation of the right amygdala Other kinds of experience elicited by the stimulation included pleasant sensations, elation, deep thoughtful concentration, "odd feelings," relaxation, and colored visions (Delgado, 1970) Delgado concluded from these observations that stimulation of this type " may have further therapeutic use in order to obtain beneficial modifications of emotional reactivity" (p 201) He also stated that it raises ethical and philosophical questions

Speech and Its Disorders

Communication is a word used in physiology with two slightly different meanings, the first of which includes the second In the more generalized sense it denotes the interaction of any two units in a fashion that modifies the function of either It may be applied to the influ-

ence of one neuron upon another, or to the stimulus transmitted between cells by a hormone, as well as to communication between persons What is transmitted is *information* In the more restricted sense communication requires signals that are created by one individual and perceived by another via sense organs The signals may be physical for optical, aural, or thermal detection, or they may be chemical The information they transmit may be extremely complex, even in relatively simple animals Perhaps the best studied example in lower forms is the ability of bees to inform other inhabitants of a hive as to the direction and distance at which a specific food source may be found (von Firsch, 1967) Ethologists and psychologists have studied many other similar kinds of communication among other animals (Dethier and Stellar, 1970)

Speech and its relatives, writing and reading, are the most elaborate forms of communication, and are limited to the human species Cortical function is necessary for speech, according to the observations of Penfield and Roberts (1966) it is the cortex of the left cerebral hemisphere that is usually responsible for speech, even in left-handed persons where the right hemisphere is said to be "dominant" for motions such as writing and other skilled performance (Fig 9 125) Geschwind (1970) has stated that, "Contrary to generally accepted views, there is a striking anatomical difference between the temporal speech region on the left side and the corresponding region of the right hemisphere "

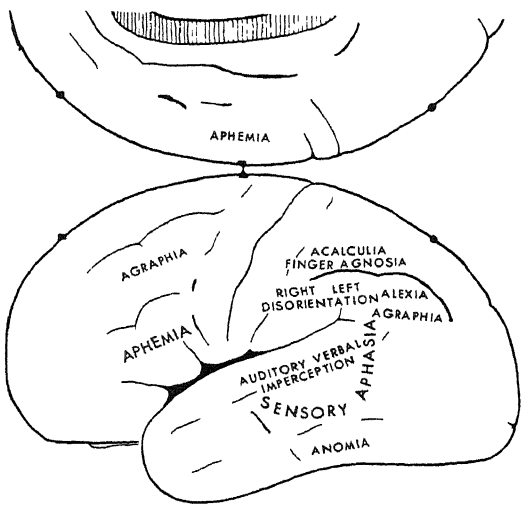

Fig 9 125 Summary of the location of cortical lesions which various authors have associated with disorders of speech (Penfield and Roberts 1966)

It is supposed that the first stage in the development of speech is the association of certain sounds—(words)—with visual, tactile, and other sensations aroused by objects in the external world After definite meanings have been attached to certain words, pathways between the auditory area of the cortex and the motor area for the muscles of articulation become established, and the child attempts to formulate and pronounce the words which he has heard This act of verbal expression involves the coordinated movements of a large group of respiratory, laryngeal, lingual, pharyngeal, and labial muscles Later, as the child learns to read, auditory speech is associated with the visual symbols of speech, and finally, through an association between these and the motor area for the hand, the child learns to express his auditory and visual impressions by the written word (see Lenneberg, 1970)

APHASIA

Aphasia is the term applied to disorders of expression in speech, writing or signs and symbols, as well as to disabilities in comprehension of spoken or written language Lesions causing aphasia are usually in the cerebral cortex, but they do not necessarily involve the motor mechanisms of area 4, the corticobulbar fibers, cranial nerve nuclei nor peripheral nerves Rather, the lesions typically lie in cortical "association" areas (Fig 9 125) near what are presumed to be the highest levels of cortical function Nevertheless, in spite of this apparent juxtaposition of localization, the intelligence of a patient may be unimpaired in the presence of severe aphasia This implies that there are functions of the cortex at levels higher than the speech mechanisms

The faculty of speech is based upon highly complex neural systems They can be studied in two ways, by analysis of defects in patients with naturally occurring lesions of the cortex or following operations, or by stimulation of the cortex at an operation in a patient given only local anesthesia for the surgical procedure The fact that this electrical stimulation is categorically different from natural neural activity is dramatically shown by the observation that in an area where a lesion causes aphasia, electrical stimulation when a patient is speaking will arrest the speech After the

stimulus is ended the patient may report that he does not know why he stopped talking, but he was unable to think of the words he wished to use There are four such areas in the left hemisphere, the dominant hemisphere in a right-handed person They include the following *1) lower frontal* cortex of Brodmann's area 4 (known as Broca's area), *2) upper frontal* on the mesial surface of the hemisphere anterior to the foot area, *3) parietal*, posterior to the lower part of the postcentral gyrus, and *4) temporal*, in the posterior part of the temporal lobe A lasting injury to any one of these areas causes persistent aphasia, with the possible exception of the one in the upper frontal region

Responses that seem to be related to speech can be obtained following electrical stimulation of other cortical regions For example, in a conscious patient a stimulus applied to the lower part of the precentral gyrus in the lips, jaw, and tongue areas of either hemisphere causes the emission of a crude sound like the cry of an infant or of an epileptic at the beginning of an attack This sound does not resemble a spoken word Similarly, stimulation in the supplementary motor area on the mesial surface of either hemisphere causes vocalization, perhaps less crude than the former but definitely not speech These kinds of stimuli are believed to be transmitted to the cortex of area 4 in a pattern that evokes vocalization as a motor act independent of the higher cortical associations necessary for speech Ablation of either of these areas causes only a temporary speech defect, perhaps motor in nature One should add, however, that operations upon the lower part of the precentral gyrus is the dominant hemisphere may cause temporarily a true aphasia This is believed to represent some interference with the function of area 44, possibly as a result of interruption of its blood supply

Classification of the Aphasias. There is no one system for classifying aphasias, the several neurologists who have studied this phenomenon having usually proposed categories that seem consistent with their own findings In this account the views of Sir Henry Head (1926), an English neurologist, are followed (Fig 9 126) Head's studies, done upon patients suffering from gunshot wounds of the cerebral cortex, led him to the conclusion that most aphasias could not be identified as

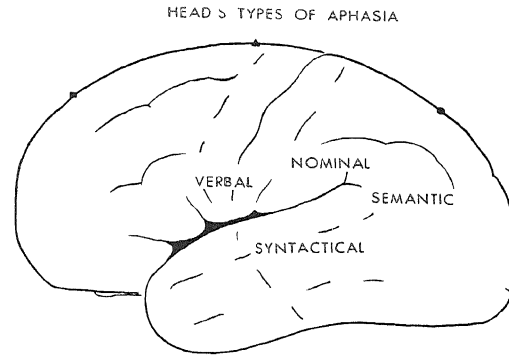

Fig 9 126 Brain map to show locations of cortical lesions responsible for types of aphasia described by Head (1926) From Penfield and Roberts 1966

simply motor or sensory in type because each patient exhibited multiple or combined deficiencies He concluded that speech mechanisms are more diffusely represented than many authors have supposed, and that the several cortical speech "centers" do not have discrete and independent functions He noted that the more complicated or abstract the idea which must be understood or expressed, the greater is the difficulty Thus, an aphasic patient may be able to name objects correctly but fails to find the word for a more abstract idea, e g , color Shown a black object, for instance, and asked to name its color he fails to do so, yet indicates that he recognizes that it is black by saying "what you do for the dead " An aphasic soldier when shown a red object said, "what the staff wear "

Head divided aphasia into four types, as follows

1) Verbal Defects The outstanding feature is that the power to express an idea in words is practically lost The patient, however, is not entirely speechless but can usually utter a few monosyllables, "yes" or "no," etc , or ejaculations and emotional expressions, such as, "damn," "oh dear me " When the disorder is less severe, the words are mispronounced but sentences are correctly constructed For such patients reading is difficult, and writing is defective or impossible They usually understand printed or oral commands

2) Syntactical Defects (Agrammatism, Jargon Dysphasia) The patient is voluble but speaks a jargon in which, though the individual words may be fairly accurately pronounced, they are strung into short phrases or badly constructed sentences without articles, prepositions, or conjunctions The ability to read

aloud is impaired, and the understanding or ordinary conversation is defective

3) Nominal (Naming) Defects In this form of speech disorder the patient has difficulty in finding the right word to express his meaning or for naming a well-known object He will often employ a descriptive phrase in substitution for the word which he cannot recall These patients can draw from a model either directly or from memory, after it has been shown and then removed, but are usually unable to draw from imagination They write a coherent letter with difficulty, usually fail to carry out simple arithmetical exercises, and confuse the values of coins

4) Semantic Defects A patient suffering from this type experiences little difficulty in articulate speech, can name objects, understands invividual words and some sentences, but the general meaning of what he hears escapes him He often fails to follow his own utterances to an intelligent conclusion, his sentences trailing off as though he had forgotten what he had started out to say When shown a picture he picks out the details but fails to grasp the meaning which it conveys to others Such a patient therefore misses the point of a joke whether this is printed, told to him, or is in pictorial form He fails to comprehend the significance of much that he sees and hears There is no impairment in the pronunciation of words and, though speech tends to be in short jerky sentences, syntax and intonation are not disturbed

Head discarded the conception that the neural basis of speech consists of strictly localized anatomical "centers" wherein resides exclusively one or other of the speech functions —auditory, visual or motor He believed, however that regions exist in the cortex "where the progress of some mode of action can be reinforced, deviated or inhibited " These regions constitute foci of integration—convergence points for association paths Destruction of one or other of such foci or "knots" of association paths will depress *as a whole* the psychological processes underlying speech Nevertheless, the nature of the speech disability is influenced by the particular region of the cortex involved If the lesion is in the neighborhood of the lower part of the precentral and postcentral convolutions of the dominant hemisphere the speech defect tends to be of the *verbal* type In injury to the temporal lobe the speech defect tends to be of the *syntactical* type In a lesion in the region of the angular gyrus of the dominant hemisphere the patient has difficulty, particularly, in finding names for things (*nominal defect*), damage to the cortex in the region of the supramarginal gyrus results in a *semantic defect*

OTHER DISABILITIES OF SPEECH AND PERCEPTION

Anarthria or dysarthria is loss or difficulty of speech due to paresis, paralysis or ataxia of the muscles concerned in articulation There is no impairment of the psychical aspects of speech, i e , "internal speech" is unaffected, there is no difficulty in the comprehension of spoken or written speech Other functions, e g , swallowing, which are dependent upon the same groups of muscles as those used in speech, are also frequently affected

Apraxia (unable to act) is the inability to perform purposeful movements at will, either at command or in imitation, though the muscles normally engaged in the act are not paralysed It is allied to aphasia, which might be called apraxia of the speech faculty Apraxia may be sensory or motor In the former, the patient does not recognize the significance of an object and therefore cannot put it to its proper use, this is *visual agnosia* In motor apraxia the patient has no conception, or a very defective one, of the pattern of muscular movement required to perform a purposeful act For example, apraxia of the tongue is frequently seen in hemiplegic patients The tongue cannot be protruded upon request, but a moment later the patient may without thought lick his lips

Agnosia (not knowing) is a defect higher than the mere inability to perceive tactile, visual, auditory or other forms of sensation, it results rather from the failure to interpret sensory impressions which enable an object, sound, or symbol to be recognized and have meaning "Word blindness" and "word deafness" are forms of visual and auditory agnosia, respectively

Astereognosis is a disorder in which though sensations of touch and muscle sense are retained, the patient cannot recognize an object placed in his hand if his eyes are closed Visual agnosia is seen in lesions of the occipital lobe of the dominant hemisphere, auditory agnosia in injury to the temporal cortex, and astereog-

nosis in lesions of the parietal lobe posterior to the postcentral gyrus

Agraphia or dysgraphia, the inability to write or difficulty in writing, may occur with visual agnosia because of a handicap in the recognition of written words, i e , a word blindness

Learning, Conditioning, and Memory

Learning is defined as a more or less permanent modification of response that occurs as a result of practice, experience or observation It is studied by testing input-output relations just as the connections of a stretch reflex through the spinal cord are studied Both the input and the output are more complex, however, the latter usually falling into the category that is known as behavior Learning has been investigated in literally hundreds of different behavioral situations, with results far too diversified for summary here Nevertheless, many of them can be classified under two major headings as being either classical (type I) or instrumental (type II) conditioning

In *classical* or *pavlovian* conditioning (Pavlov, 1928), the stimulus to which the subject is to be conditioned is always followed by the unconditioned stimulus, perhaps food, or an electrical shock The subject has no control over receiving, avoiding, or escaping the unconditioned stimulus, and the conditioned response when it develops seems to come in spite of rather than by the intention of the subject

Instrumental conditioning, on the other hand, refers to procedures in which the subject's behavior to the initial stimulus determines whether or not the subsequent stimulus is presented Thus, the pressing of a bar after the initial stimulus is presented may bring about a reward such as delivery of food, or prevent a punishment such as an electric shock Conditioning has occurred when the subject has learned to make the appropriate response to the initial stimulus

Classical Conditioning

It was Pavlov (1928) who, in the course of extensive studies on the physiology of the digestive glands, first began a systematic experimental investigation of conditioning phenomena Basically, the experimental procedure for classical conditioning involves the repeated pairing of two stimuli: *a*) an *unconditioned stimulus* (UCS) which at the beginning of the experiment evokes a regular and measurable response called the unconditioned response (UCR), and *b*) a *conditioned stimulus* (CS) which initially is ineffective (neutral) and does not elicit the UCR at the outset of the experiment Following repeated presentations of the conditioned stimulus and the unconditioned stimulus, a response resembling the unconditioned response may be elicited upon presentation of the conditioned stimulus alone Such a response is called the *conditioned response* (CR)

CLASSICAL CONDITIONING EXPERIMENT

In most of the conditioning experiments performed by Pavlov, the secretion of saliva was chosen as the response to be measured A ticking metronome (CS) was presented a few seconds before a small quantity of meat powder was blown into the dog's mouth The food, elicited a certain amount of salivation (UCR) which was measured After a certain number of pairings, the sound of the metronome alone (the food being withheld) elicited the secretion of saliva Pavlov called this response a conditional reflex, meaning that the occurrence of the response to the previously neutral cue was literally conditional upon certain operations, namely, the repeated pairings of the neutral cue (CS) with the unconditioned stimulus The original Pavlovian procedures of classical salivary conditioning were subsequently modified by Bekhterev (1933) He substituted an electrical shock to the hind legs of dogs in place of food as the UCS and studied withdrawal and respiratory responses evoked by the noxious leg shock After repeated pairings of the sound of a metronome (CS) with the electric shock (UCS), the CS evoked a conditioned leg flexion.

ELECTRICAL RECORDINGS

Two major classes of bioelectrical events which have been measured during conditioning are *a*) spontaneous electrical activity of the brain (the electroencephalogram or EEG) which has been observed to vary in frequency, amplitude, and other properties during different phases of conditioning, and *b*) electrical activity evoked by a stimulus (e g , light flash, tone, touch) which may show systematic changes in amplitude and wave shape when

the stimulus is paired with an appropriate UCS The prototype of bioelectrical conditioning is the conditioned blocking of the occipital α rhythm (8 to 12/sec frequency) which was first observed by Durup and Fessard in 1936 These workers discovered that the click of a camera shutter used to photograph α blocking elicited by light sometimes produced attenuation of the α activity Previous testing had shown that the noise of the shutter alone had no effect on the electroencephalogram Study of this form of conditioning then began in many other laboratories, and Jaspar and Shagass (1941) were able to duplicate nearly all the phenomena of classical conditioning (e g , extinction, discrimination, delayed, and trace conditioning)

The latency, magnitude, and duration of evoked potentials in the cerebral cortex have been studied during conditioning with both macro- and microelectrode techniques For example, in a detailed study on cats and monkeys, Galambos and Sheatz (1962) used chronically indwelling electrodes in different brain regions for the study of evoked potentials elicited by clicks and light flashes (the CS) A puff of air to the face was used as the unconditioned stimulus Prior to conditioning trials, the CS was presented many times to habituate the evoked response to the click When presentation of the CS resulted in no further change in the amplitude of evoked potentials, conditioning trials were started with the click regularly followed by the puff of air (UCS) The evoked potential to the click increased in amplitude following a few pairings of the CS and UCS (Fig 9 127)

Cerebral cortical activity has been studied also by the use of microelectrode techniques to monitor single cell discharges during conditioning (Jasper, Ricci, and Doane, 1960, Yoshii and Ogura, 1960). These studies suggest that changes in single cell discharge rates do occur during conditioning, although there is great variability associated with the response In the typical experiment, an exteroceptive light flash (the CS) is paired with an appropriate unconditioned stimulus (e g , shock to paw or sciatic stimulation) and the unconditioned response recorded is either an increase or decrease in the discharge rate of individual neurons. After repeated pairings, the light alone is able to evoke the characteristic discharge rate previously associated only with the unconditioned stimulus Repeated extinction and reconditioning of single cells has been reported to occur with this procedure (Kamikawa et al , 1964)

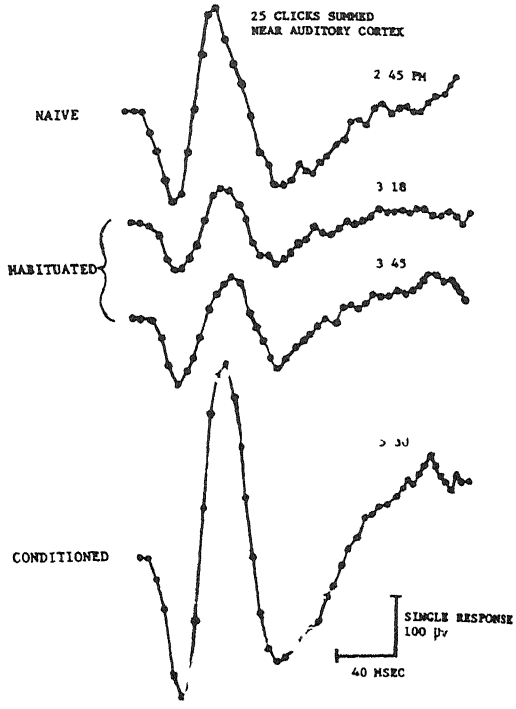

Fig 9 127 Cortical potential records averaged by computer to show response of auditory cortex to sound of a click *Naive* response before habituation *Habituated* response after repeated stimulation *Conditioned* response to click plus puff of air to face (Galambos and Sheatz 1962)

ELECTRICAL STIMULATION

Another technique has been the use of direct brain stimulation as either the conditioned or unconditioned stimulus As might be expected, interruption of the afferent fibers of an exteroceptive conditioned stimulus prevents the acquisition and the performance of a conditioned response However, direct electrical stimulation of the spinal cord, cerebellum, and various areas of the cerebral cortex may be substituted for normal exteroceptive stimuli, and serve as conditioned stimuli For example, instead of pairing an exteroceptive light (the CS) with food (the UCS), electrical stimulation of the occipital region may be paired with the UCS With this procedure, conditioning takes place in about the same number of trials as when normal exteroceptive signals are used as

conditioned stimuli Even electrical stimulation of nonsensory areas of the cortex has been used successfully as a conditioned stimulus It has also been possible to obtain successful conditioning where both the conditioned and unconditioned stimuli are applied to the cortex electrically (Doty, 1961)

Instrumental Conditioning

If the response of the animal can affect the occurrence or duration of the UCS, then the procedure becomes one of instrumental conditioning The most common instrumental procedures used in the study of the neurophysiology of behavior may be classified as *a*) escape and avoidance conditioning, *b*) operant conditioning, *c*) discrimination learning, and *e*) problem-solving learning The same parameters of conditioning (generalization, extinction, etc) discussed for classical conditioning procedures are also found in instrumental conditioning procedures

ESCAPE AND AVOIDANCE CONDITIONING

In *escape* conditioning, the animal can terminate an aversive stimulus by making an appropriate response In *avoidance* conditioning, the response prevents the delivery of the aversive stimulus The most common responses studied have been paw-withdrawal, jumping, lever pressing, wheel-turning, and shuttling In this last procedure, the animal is placed in a two-chambered box with the two compartments separated by a hurdle, a swinging door, or a line on the floor In order to avoid shock, the animal has to learn to respond to a signal (the CS) by shuttling or hurdling from one compartment into the other compartment This is an example of an *active* task in which the animal must move or make some other response to avoid the UCS Other procedures, where the animal must inhibit a previously learned response to avoid an aversive stimulus, are cases of *passive* avoidance For example, in passive avoidance an animal may be tained to enter a compartment or to insert its head into a tray for food when a CS is presented After the animal has learned this response, an aversive stimulus is then presented whenever the animal enters the compartment or inserts its head into the tray when the CS is presented The animal, in order to avoid the shock, must now learn to withhold his approach to food The behavior of not approaching food is passive avoidance, whereas an animal that must move or make some active response (turning a wheel) is displaying active avoidance

OPERANT CONDITIONING

The development of operant conditioning procedures is closely associated with the experimental analysis of behavior by B F Skinner (1938) and his associates In the typical "Skinner box" situation, a hungry rat is placed in a dimly lit box which has a movable lever connected to an electric switch The rat explores the box and occasionally by chance presses its paws upon the lever The number of presses for some arbitrary time period defines the rat's *preconditioning operant level* of bar pressing The food magazine is then connected to the switch so that when the rat presses the bar a pellet of food falls into a dish The rat eats, and soon presses the bar again The delivery of foot pellets (the click of the food magazine, the food dropping into the food tray, etc) "reinforces" bar pressing The number of lever presses plotted against time provides a record of the course of operant conditioning (or operant rate) Often, the untrained rat is *shaped* to perform the desired bar pressing response by the procedure of *successive approximations* For example, food is delivered whenever the hungry rat approaches the bar, then whenever it touches the bar, and finally only after it presses the bar

In operant conditioning the animal must make a response before the response can be reinforced Skinner (1938) called this behavior "operant" because the behavior of the rat operates on the environment The operant conditioning situation differs from both classical and avoidance conditioning in that *a*) there is no specifiable unconditioned stimulus which elicits the response, and *b*) the animal is free to respond at any time in the operant situation, but is usually given discrete trials in avoidance and classical conditioning Operant techniques have been used in the experimental analysis of the behavior of a wide variety of animals including humans. The objective of operant techniques is to place some arbitrary sample of behavior under experimental control so that behavioral processes may be investigated as a function of a wide variety of conditions

Reinforcement: Definition and Parameters. The term reinforcement is commonly used when discussing operant conditioning, although the pairing of the conditioned and unconditioned stimulus in classical conditioning is also called reinforcement A reinforcing stimulus may be operationally defined as a stimulus which alters the probability of occurrence of the response that precedes it Reinforcing stimuli (reinforcers) may be either positive (e g , food, water) or aversive (e g , electric shock) The quantity and quality of the reinforcement as well as the interval between the response and the presentation of the reinforcement (called delay of reinforcement) are important variables which affect the organism's behavior during learning (cf Kimble, 1961) Another important variable is the schedule of reinforcement Reinforcement may be given on every trial or after every correct response (*continuous reinforcement*) or intermittently, that is, the response is reinforced only part of the time The main effect of such an *intermittent* or *partial reinforcement* is to make it more difficult to extinguish the response once it has been learned The effect of intermittent reinforcement is found in both operant situations and discrete trial instrumental tasks Partial reinforcement in the operant situation may be delivered on either a temporal (interval) schedule or on a response (ratio) schedule Further details about these techniques should be looked for elsewhere, for example, in Kimble (1961) or in textbooks of psychology

Electrical Self-Stimulation of the Brain. The discovery that low voltage electrical stimulation of various brain loci may be used as positive and negative reinforcement has led to numerous self-stimulation studies In these studies, stimulating electrodes are chronically inserted into subcortical structures and connected by a light flexible cord to a source of stimulating current The animal, by pressing a bar or lever, delivers a flow of stimulating current to its own brain The electrical circuit is constructed so that a fixed duration of stimulating current is delivered for each bar press Thus, the experimental procedure is the same as other operant techniques, except that instead of receiving a food pellet as reinforcement, the animal receives a slight shock to its brain

Olds and Milner (1954) were the first to discover that rats, allowed to stimulate their own brains, would maintain high lever pressing rates over long periods of time without any other reward This interesting and important finding has resulted in extensive experimentation and speculation concerning the variables which influence brain self-stimulation Some of the variables shown to be critical determinants of this phenomenon are the specific anatomical locus of the electrode, the intensity of the stimulating current, the schedule of brain reinforcements, and food and water deprivation For example, rats with electrodes in the lateral hypothalamus will, under continuous reinforcement, press about 10,000 times an hour for brain stimulation but only about 500 times an hour when the electrodes are in the septal or amygdaloid areas With electrodes in the periventricular system of fibers (dorsal longitudinal fasciculus of Schutz), rats will actively work to prevent or escape the brain stimulation Stimulation of certain medial hypothalamic areas yields both positive and negative effects With electrodes in these brain sites animals can be trained to turn on the brain stimulation and then immediately turn it off (cf Olds, 1962) The rewarding effects of intracranial self-stimulation have also been observed in cats, monkeys, and humans (Sheer, 1961) During neurosurgery of humans, stimulation of various brain loci has resulted in verbal reports of feelings of joy and satisfaction and experiences of tickling and fluttering of muscles in the pelvic region which were regarded as pleasurable The patients, given a key which controlled the delivery of the brain stimulus, would eagerly respond by self-stimulation

DISCRIMINATION LEARNING

Discrimination learning is involved in every learning situation, but has been studied most extensively with instrumental procedures The general procedure used to establish a discrimination involves the extinction of responses to certain stimuli by withholding reinforcement, while a response to some second stimulus is maintained by the delivery of reinforcement The discrimination experiment was originally designed to test the sensory capacities of various animals At present, discrimination behavior is often studied as a learning phenom-

enon in its own right The two methods of presenting stimuli in discrimination experiments are *a*) successive presentation of stimuli (contrasts), and *b*) simultaneous presentation of stimuli (choice response)

Types of Discrimination Task Visual, somesthetic, and auditory discriminations have been studied in a variety of instrumental conditioning procedures The most intensively studied of all types of discrimination has been visual discrimination—particularly form discrimination In the typical discrimination task with primates, two stimulus objects which may differ in either shape, size, or color are placed over two food wells on a test tray (Fig 9 128) The food well under the correct object is baited with food and the other food well is left empty The animal must learn to select the correct stimulus and move it aside to pick up the food in the well The positions of the objects on the tray are shifted from one side to the other in either a random or balanced order Between trials, a screen is lowered in front of the monkey so that the appropriate food well may be baited Information about these and other procedures used in behavioral testing of primates may be found in the volume edited by Schrier et al (1965)

PROBLEM-SOLVING PROCEDURES

Problem-solving instrumental procedures are no doubt the most familiar of the animal testing procedures developed by psychologists Originally, many of the so-called problem-solving tasks were designed to test for symbolic behavior in lower animals Now, it is generally assumed that the animals learn problem-solving tasks in the same way as other instrumental tasks are learned, except that the discriminative cues are more subtle or complex in the problem-solving tasks Problem-solving procedures have been classified as learning with complex cues (cf Ratner and Denny, 1964) In general, the following types of learning tasks may be distinguished

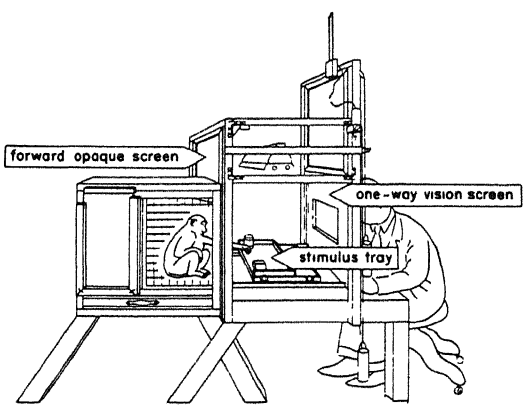

Fig 9 128 General test apparatus for studying learning by way of discrimination performance In this form it is known as the Wisconsin or the Harlow apparatus

Maze Learning. Discrimination learning in either a T-maze or a Y-maze is one of the most widely used instrumental learning techniques The discriminative cue may be either spatial or nonspatial In a spatial problem, the animal chooses between a pair of stimuli which differ only in their position in space The animal, for example, may be required always to turn left or choose the left door in order to receive reinforcement In a nonspatial problem, the two discriminative cues each appear in the two positions in a random order, and reinforcement is correlated with the positive cue For example, in a red-green visual discrimination, the green alternative may be reinforced independently of its position Spatial and nonspatial problems may also be used in complex mazes For example, at each choice point the animal may be required always to turn left (spatial) or to turn into the lighted alley in a light-dark nonspatial discrimination problem

In some cases, the animal's own response may be the cue for the correct response at the next choice point For example, in a *simple-alternation* problem, the animal must alternate left and right turns (LRLR) in a 4-choice maze Turning left at the first choice point provides the cue for the right turn at the next choice point and so on Most mammals can readily learn a simple alternation problem as they tend normally to alternate spontaneously in most maze situations. A more difficult problem is the *double-alternation* pattern (LLRR) Rats, typically, fail to learn a double-alternation problem, whereas other mammals (cats, dogs) are capable of learning a LLRR problem but fail to learn a longer sequence

Delayed Response. The delayed-response problem is one of the most sensitive behavioral tests and has been used in neurobehavioral research to detect the effects of brain lesions, drugs, and radiation The delayed-response

problem is particularly sensitive to damage to the central nervous system, especially the frontal lobes In this problem, the animal is presented a limited number of choices where food might be placed The animal is first trained to respond to a particular stimulus in order to obtain food The animal is then restrained from approaching the food compartments or the stimuli over the food wells until released The experimenter at the beginning of the trial permits the animal to see where the food is located by turning on a light over the correct food compartment (indirect method) or by directly placing food into a particular food well (direct method) The light is then turned off or a screen is lowered in front of the animal, and following a certain delay, the animal is allowed access to the compartments or food wells The purpose of the testing procedure is to determine how long the animal can be delayed without "forgetting" where the food has been placed This task commonly has been used to determine if an area of the brain is involved in immediate memory

MECHANISM OF CONDITIONING

One of the oldest theoretical controversies in learning theory concerns the question of just how does conditioning occur Pavlov believed and many authors after him assumed that classical conditioning is a neocortical phenomenon It was supposed to be the only level of the nervous system with the plasticity necessary for development of what appear to be new connections between stimulus and response Later experiments showed, however, that conditioning can be induced in decorticate animals (Hilgard and Marquis, 1940), and in spinal preparations (Dykman and Shurrager, 1956), albeit only after prolonged training using intense stimuli Still more recently single neurons have been found to exhibit responses that are considered to be conditioned (Tauc, 1967) Consequently, the capacity for conditioning is now regarded as a generalized property of neurons, not necessarily dependent upon the organization of a higher nervous system

Another point of uncertainty has been the relation of somatic muscular movement to conditioning, because it was supposed that a feedback to the nervous system from skeletal muscles was needed for the conditioning process The truth of this concept has been tested through the use of drugs, e g , curare, that block somatic movement Conditioning does occur in animals under the influence of curare, and the conditioning persists into the postcurare period (Black et al , 1962, Solomon and Turner, 1962) In fact, Miller (1969) has reported that "learning" was actually facilitated by administration of curare He suggested that this was because the drug removed " interference from skeletal responses and distraction from irrelevant cues" (p 444)

AUTONOMIC CONDITIONING

A closely related question is whether conditioning can take place in the autonomic nervous system, independently of somatic motor response One of the principal problems has been the exclusion of somatic movements that might have produced secondarily what appeared to be a conditioned autonomic response For example, although heart rate is completely under autonomic control and should be a good subject for a test of conditioning, it is modified also by changes in the respiratory pattern that are brought about through somatic nerves What is clearly autonomic conditioning, however, has been demonstrated by Miller (1969) and his associates Using instrumental techniques they observed in rats the conditioning of salivation, heart rate, intestinal contraction, glomerular filtration, renal blood flow, and the rate of urine formation (Fig 9 129) By appropriate reinforcement they could either increase or decrease any of these variables Their experiments, therefore, confirm the conclusion that conditioning is a much more common or generalized phenomenon than most of the earlier authors had supposed

NEURONAL CONDITIONING

In higher animals because of the multiplicity of neurons and pathways involved in learning and/or conditioning, it has been extremely difficult to discover cellular correlates of the conditioning process Lower animals, by contrast, have simpler nervous systems and lend themselves to study of fundamental processes in single cells The discovery that these lower forms exhibit conditioning has revolutionized this field of study In the gastropod, *Aplysia*, the neurons of the abdominal ganglion are large, they are practically uniform in appearance and location from one animal to another,

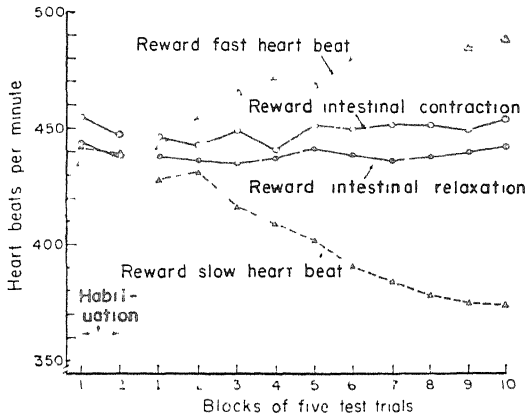

Fig 9 129 Learning curves for rats in which heart rate was recorded during experiments where reward was provided by stimulation of the brain All records portray rate of heart beat but the physiological change for which reward was given was different for each curve The two middle records show that rewarding changes in intestinal contraction did not alter heart rate Miller and Banuazizi 1968 cited from Miller 1969

they have identified connections, and can be penetrated under microscopic observation with microelectrodes for recording of transmembrane potentials, for intracellular stimulation or for microinjection Using these techniques the properties of their membranes have been described, synaptic potentials have been recorded, and the role of chemical transmitters has been clarified (Tauc, 1967) With reference to these properties these neurons are not unique, but rather serve as convenient examples of what happens in nerve cells upon stimulation Their value in the study of conditioning, however, is derived from the disclosure that their sensitivity to stimulation is a function of their immediate history (Tauc, 1967, Kandel and Spencer, 1968) Whether or not a cell will respond to a stimulus of a given strength depends upon whether or not it has been previously stimulated, and the conditions of the previous stimulation Furthermore, when stimuli are delivered via two different afferent nerves they interact at the synaptic membrane of the ganglion cell in a fashion that appears to simulate pavlovian conditioning These and related observations have given a strong impetus to theories in which conditioning and learning are regarded as localized changes in or on the surface of neurons Although there seems to be no doubt that in higher nervous systems and in more complex responses the phenomena of conditioning, learning, and memory involve pathways and circuits rather than single cells, yet what happens in a circuit must be determined ultimately by the state of the cells that comprise it One may suppose that *learning* is characterized by physicochemical changes in cells as a result of *conditioning*, and that these changes in turn create the possibility of *memory*

Memory

The exact nature of the changes in the nervous system that constitute the memory trace remains unknown There are, however, a number of studies that shed some light on this fascinating problem (See John, 1967, Byrne, ed , 1970)

One of the early speculations concerning the establishment of the memory trace is generally attributed to Muller and Pilzecker (1900) In order to account for the phenomenon of decreased retention of recently learned material when another activity intervenes between initial learning and retention testing, Muller and Pilzecker proposed the existence of a neural perseverative process This perseverative process was presumed to be easily interfered with by external influences and was also considered necessary to the "consolidation" of the memory trace for recently learned material Most of the more recent investigators have accepted this concept, namely, that the establishment of a memory trace takes place in two stages, an initial stage in which the memory trace is evanescent and easily disrupted, and a later, more stable state, dependent on the initial process and which is the "permanent" memory trace

For many years the only evidence in support of such a proposal was the retrograde amnesia seen in many patients after cerebral trauma Head injuries are often followed by loss of memory for events occurring during the period preceding the injury With the advent of electroshock therapy for psychoses in the late 1930's, further evidence for this two-stage nature became available Shock is administered through electrodes applied to the skin of the head It leads to unconsciousness, and presumably disrupts by electrical energy much if not all of the neuronal circuits of the brain—at least temporarily Many physicians and investigators who used or studied electroconvulsive shock (ECS) found that it too produces a dif-

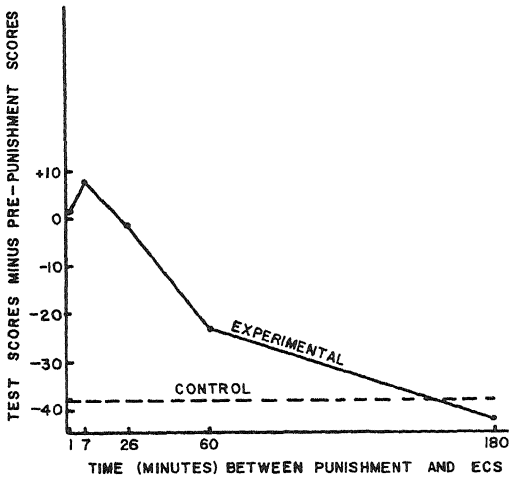

Fig 9 130 Effect of electroconvulsive shock (ECS) on retention as a function of the time interval between the learning experience and the application of ECS The data show that if the interval between learning and ECS is as long as 180 min the ECS does not prevent learning retention (Heriot and Coleman 1962)

ferential loss of memory only for events immediately preceding the shock treatment (e g Williams, 1950) The time course of the effects of ECS on the memory trace has since been explored in a number of studies For example, Heriot and Coleman (1962) trained rats to press a lever for a food reward Then the lever was electrified so that the animals received a slight shock when the lever was touched After this, animals avoided the lever The animals were divided into groups which received also an ECS at intervals ranging from 1 to 180 min after the initial, slight shock Control animals and animals receiving ECS 180 min after being shocked by the lever showed a significant decrease in number of lever pressings Animals receiving ECS within an interval of 26 min pressed the lever at the same rate as before being shocked, they apparently did not remember their unpleasant experience with the lever (Fig 9 130) Other studies have shown that this consolidation phase may require from about 15 min to possibly several months (Gellhorn, 1945), depending on the learning situation and on the procedure used in disrupting the consolidation Other procedures that have been successfully utilized to disrupt the consolidation phase include hypothermia, insulin coma, Metrazol convulsions, anoxia, some anesthetic agents and application of chemicals or electrical stimulation to local regions of the brain

NATURE OF THE STAGES

If the sequence of conditioning-learning-memory is analogous to other types of neural activity, then it must depend ultimately upon conduct of nerve impulses through circuits of neurons Perhaps the simplest way in which this can be described is to suppose that when a sensory field, for example, is registered upon neurons of the cerebral cortex (phase I, Fig 9 131), the circuit through which the activity was carried from brainstem to cortex becomes temporarily self-exciting, because of changes of the type exhibited by *Aplysia* ganglion cells, as described above (phase II, Fig 9 131) This activity may or may not become evident at the level that is called consciousness, but because the circuit remains in action its activity can be diverted to the conscious level rather easily where it becomes evident as memory During the time that the sensory information is stored in such a circuit it can be either retrieved or it can be destroyed, as in the case of ECS treatment This is the initial stage of learning, the stage of "registration" (Jarvik, 1970) Inasmuch as all neural activity is based upon physicochemical changes both along axons and at synapses, this stage must have such a basis

If the activity in the circuit is intense enough, or if it persists long enough, it is assumed to create more nearly permanent changes in the neurons involved (phase III, Fig 9 131) As a result of these changes any of the cells that carried the activity is likely to re-establish the complete circuit whenever it is activated This means that a circuit that in the first instance was integrated into a pattern because of repetitive neural activity has now been altered so that the pattern tends to be reassembled because of some structural or

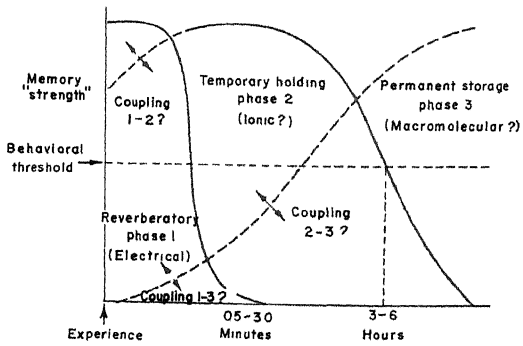

Fig 9 131 Relation of time to "strength" of memory, with curves showing hypothetical duration of three phases in memory process (John, 1970)

chemical change in its elements This is the stage of "retention," brought about by "consolidation" The nature of the alterations that convert phase II into phase III has been studied in many laboratories, with results that are fascinating even though as yet they are not entirely consistent in their significance

CHEMICAL CORRELATES OF MEMORY

There are many indications that intracellular protein synthesis involving ribonucleic acid (RNA) may play a vital role in the long-term memory trace RNA is a substance capable of preserving a structural modification by continually imposing on molecules being formed with neural tissue a structure that could be determined by learning and experience One of the first to suggest that RNA might be this substance was Hyden (see 1962), who showed that stimulation of the brain tissues of rats and rabbits caused an increase of RNA in the neurons In later studies Hyden dissected out, and chemically analyzed, single cells from the lateral vestibular nucleus of rats trained to climb and balance on a steel wire inclined at a 45-degree slope, in order to obtain food He found that significant changes took place in the composition of the nuclear RNA Of the four amino acids that form RNA—adenine, cytosine, guanine, and uracil—Hyden found an increase in adenine and a fall in cytosine

More recently there have appeared reports of studies which suggest that RNA altered by learning may transfer the memory trace from a trained animal to a naive animal One group (Babich et al , 1965) trained one group of rats to press a lever for food in a Skinner box only when a blinking light was on Another group of rats was trained to press a lever for food only when a click was sounded RNA was then extracted from the brains (excluding cerebellum, brainstem, olfactory bulbs, and prefrontal areas) of these animals and injected intraperitoneally into untrained rats Some of the untrained rats received RNA from light-trained rats, other received RNA from click-trained rats The untrained rats were then tested in a Skinner box for number of lever presses, with both click and light flash (at separate times) The click-injected group responded more to click than to light, and the light-injected group responded more to light than to click

Dingman and Sporn (1961) studied the effects of 8-azaguanine on learning in rats in a water maze 8-azaguanine is so similar to the guanine component of RNA that enzymes responsible for RNA synthesis will employ the 8-azaguanine rather than guanine and proceed to manufacture an RNA quite unlike the usual product The administration of 8-azaguanine did not affect the ability of rats to swim through a maze learned some time beforehand, that is, it did not affect recall and performance of a well-established memory trace Dingman and Sporn next injected rats with 8-azaguanine and then tried to teach them to swim a new maze The injected rats made twice as many errors as a control group, suggesting that the formation of new memory traces is depressed when RNA synthesis is interfered with

Research on this problem, however, has become one of the most controversial topics in neurophysiology, in part because the results reported have seemed inherently implausible to many investigators, and in part because of reports that certain of the results could not be verified The literature is much too large for evaluation here, further information is available in the proceedings of a recent conference on the subject (Byrne, editor, 1970)

Another means of studying the chemical basis of memory is to alter the synthesis of the protein that is guided by the cellular RNA Thus Flexner et al (1963) reported that previously stablished memory traces are disrupted when animals are given injections which may suppress protein synthesis by neuronal RNA Mice were trained to run to one arm of a Y-maze At various times after training, the animals were given local intracerebral injections of puromycin, an antibiotic which inhibits protein synthesis in vivo The intracerebral injections were administered bilaterally in either the temporal region, the ventricular region, or the frontal region and all combinations of these sites Short-term memory was lost only with the temporal injections Loss of longer-term memory required puromycin over basically the entire cortex and possibly the thalamus as well

The results of these experiments seemed clearcut when they were first presented, but subsequent work has altered some of the interpretations originally offered (Dethier and Stellar, 1970) The principal complication is that puromycin has effects other than the inhibition of protein synthesis, one of which is that it al-

ters cerebral electrical activity (see Barondes, 1970). The reason for this alteration is not known, but it apparently is not a direct consequence of the blocking of protein synthesis, inasmuch as other blocking agents do not lead to these electrical changes. Puromycin is assumed to evoke a subconclusive electrical activity in the cortex, which in itself might have an effect on memory consolidation. Nevertheless, another blocking agent, acetoxycycloheximide, likewise interferes with retention of learned behavior without altering the cortical EEG. This supports the original conclusion that protein synthesis is required for consolidation (Barondes, 1970; Agranoff, 1970). The data currently available are in agreement with the hypothesis that repetitive activity in a neuronal circuit leads to changes in RNA composition, as a result of which protein synthesis is altered in a fashion that permanently establishes the possibility of reactivation of that particular circuit.

No studies have delimited any single region of the brain as *the* site of long-term memory. Many studies have shown deficits in the retention of specific tasks after extirpation of localized portions of cortex or subcortical structures without any generalized deficit of long-term memory per se. For example, a learned auditory intensity discrimination task is lost after removal of auditory cortex (Raab and Ades, 1946). However, tasks involving other modalities are not lost, and the auditory intensity discrimination can be relearned. It seems, although the capacities necessary for performance of the task may have resided in the cortex in the intact animal, subcortical centers were capable of providing the requisite capacities for learning the discrimination after the cortical removal (as noted above). Current evidence, then, indicates that the capacity for long-term memory is widely diffused throughout the nervous system with the memory trace stored in multiple locations in the intact animal.

DISORDERS OF NEURAL CONTROL

It is obvious that lesions at various points in the nervous system are likely to produce different manifestations These differences may be revealed as disorders in somatic muscular activity Many such disorders have been referred to in preceding chapters because of the insight they provide into normal functions of the several parts of the brain and spinal cord This chapter is devoted to brief consideration of selected but typical clinical syndromes, presented in accordance with the concept of levels of function as in foregoing pages

Significance of the Level of a Lesion

Destruction of the peripheral nerves supplying a skeletal muscle produces an easily understood clinical picture The muscle is *1)* totally paralyzed, it is beyond the patient's control, and he cannot move it, *2)* no reflex activity of any sort is possible, although in the early stages the muscle may still contract in response to direct percussion or direct stimulation with a galvanic current, and *3)* the muscle wastes away to a useless fibrous cord because it is devoid of innervation and completely without use Involvement of this sort is often spoken of as a "lower motor neuron" paralysis and it may develop following destruction of the anterior horn cells in the spinal cord, or following division of the anterior spinal roots or of the muscular nerve One must never forget, however, that not all paralyses are complete Some innervation may remain and then the muscle is weakened but not completely paralyzed, the reflexes are diminished but not abolished and the wasting is incomplete

Although the term "lower motor neuron" paralysis is accurate for the condition described above, it has the disadvantage that it implies that there is a counterpart, an "upper motor neuron" paralysis This is misleading for there is no constant reliable entity which can be so designated The manifestations of involvement of the many neurons which lie above the anterior horn cell which are responsible in one way or another for some phase of muscular activity vary widely depending upon which such neurons or groups of neurons are involved Thus, a severe paralysis with spasticity and hyperactivity of the stretch reflexes may occur if the descending motor pathways in the internal capsule are involved If, on the other hand, the lesion is limited to the corticospinal fibers in the central portion of the cerebral peduncle one sees a loss of some fineness and delicacy of movement with little or no spasticity and little increase in tendon reflexes Lesions of the globus pallidus combined with destruction of the substantia nigra are characterized by increased resistance to passive manipulation of the extremities, with a generalized rigidity of the body and a loss of the facial movements of expression and of many automatic associated muscular movements but with little or no true paralysis and little if any change in the tendon reflexes As noted before a paralysis arising from a lesion in the internal capsule is commonly associated with a flexor spasticity in the upper extremity and an extensor spasticity in the lower extremity, whereas a severe lesion in the mesencephalon is likely to produce a paralysis with extensor spasticity in all four extremities In contrast to this, a transverse lesion of the spinal cord will produce a complete paralysis of voluntary movement in the skeletal musculature below the level of the lesion, with a variable reflex pattern, depending upon the location of the lesion and the pathways which are involved One reflex seems to have its own specific significance—the *sign of Babinski* (see below) This is a sign of interruption of the corticospinal fibers which innervate the musculature of the great toe, it is not a sign of damage to any other corticospinal fibers

Both "upper" and "lower" motor neuron paralyses may be associated with atrophy or wasting of the involved muscles Muscular wasting is in general proportionate to the degree of loss of use of the muscle rather than to

loss of innervation Wasting from "upper motor neuron" lesions is never complete because even with a *total* paralysis of voluntary activity some reflex activity persists

Lesions at various levels are likely to involve other structures, and thus indicate their location by the nature of the other clinical manifestations which the patient develops (Fig 9 132) Thus, a massive lesion of the internal capsule will produce a contralateral hemihypesthesia and possibly a homonymous hemianopia as well as a hemiplegia A unilateral lesion in the midbrain often will produce a third cranial nerve palsy (with a ptosis of the upper eyelid, a paralysis of several ocular muscles, a dilatation of the pupil and a loss of the pupillary light reflex) on the side of involvement in addition to a contralateral spastic hemiplegia Lesions involving one half of the lower brainstem may be associated with a paralysis of one or more cranial nerves (e g , facial, vagus or hypoglossal) on that side of the body and a hemiplegia and hemianesthesia on the opposite side of the body In contrast with this a unilateral lesion of the spinal cord produces what is known as a Brown-Sequard syndrome—a paralysis of the skeletal muscles of the trunk and extremities and a loss of position and vibratory sensibilities below the level of the lesion and on the same side, with a loss of pain and thermal sensibilities on the opposite side (Fig 9 133) Obviously the possible combinations of symptoms and signs are numerous and cannot all be discussed in detail here Their recognition and proper interpretation are dependent upon a thorough understanding of the structure and function of the nervous system

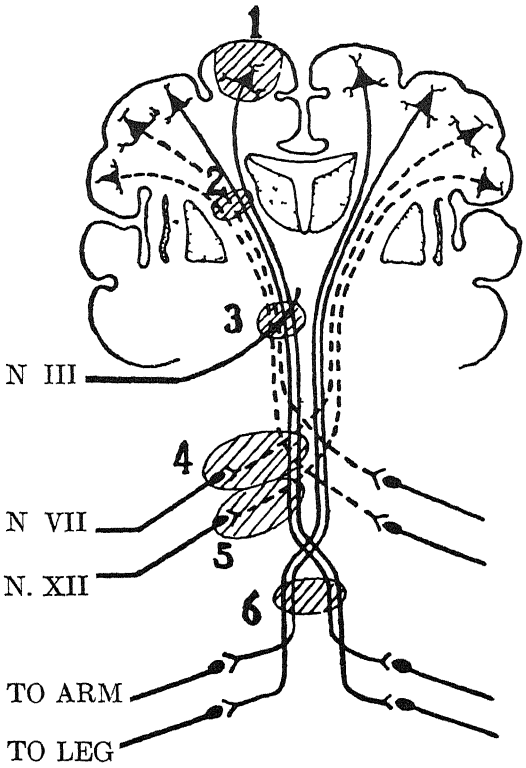

Fig 9 132 Diagram illustrating the clinical signs that follow typical lesions of the central nervous system *1)* Lesion of cerebral cortex causes monoplegia or hemiplegia depending upon its extent 2) Lesion in internal capsule may cause hemiplegia *3)* Lesion of midbrain may involve descending motor fibers to opposite side of body and an ipsilateral eye muscle nucleus *4)* or *5)* Lesion in pons or medulla has results similar to location *3,* but involving other cranial nerves *6)* Transection of spinal cord causes paraplegia

It is evident that the paralysis is more likely to be bilateral if the lesion is situated in a region where, as in the brainstem or spinal cord, the descending motor tracts of the two sides are approximated, than if it is located at a level where these tracts are widely separated, as in the corona radiata or internal capsule, then unilateral effects are usual Complete interruption of the spinal cord will of course result in paralysis on both sides of the body below the level of the lesions—*paraplegia* (see next paragraph)

Lesions of the Spinal Cord

TRANSVERSE DIVISION OF THE SPINAL CORD

A sudden, or rapidly progressive, complete interruption of the continuity of the cord may result from injury (e g , gunshot wound, fracture-dislocation of the spine, etc) or from acute inflammation (e g , transverse myelitis) Immediate and complete loss of voluntary power below the level of the lesion results Paralysis of both lower limbs resulting from this or any other nervous lesion is spoken of as *paraplegia* Complete division of the cord in the lower cervical region will result in paralysis of all four limbs, *quadriplegia* A lesion of this nature in the upper cervical region is of course rapidly fatal since the diaphragm and other respiratory muscles are isolated from the respiratory center

Stage of Spinal Shock Immediately fol-

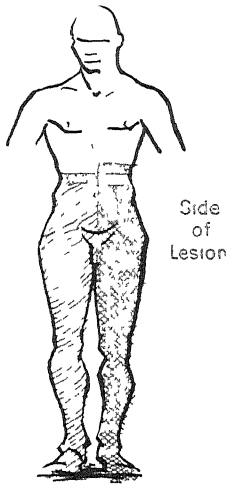

Fig 9 133 Illustration of motor and sensory deficits following hemisection of the lower thoracic spinal cord Narrow white band at level of lesion indicates total anesthesia and analgesia ▨ Analgesia thermo anesthesia and partial loss of tactile sense ☐ Cutaneous hyperthesia ■ Motor and vasomotor paralysis loss of joint muscle vibratory sense

lowing the injury there is complete loss of visceral and somatic sensations, and flaccid paralysis below the level of the lesion The skeletal muscles are quite toneless The tendon jerks, plantar response, and abdominal reflexes are abolished The cremasteric and bulbocavernosus reflexes, though absent as a rule, may at times be elicited The anal reflex is present A zone of heightened sensitivity (hyperesthesia) immediately above the level of the lesion may be present and spontaneous pains in this region, or a feeling of tightness encircling the body may be experienced by the patient There is retention of urine and feces This stage is analogous to the state of spinal shock in lower animals but is much more severe and prolonged (chap 5) In man spinal shock lasts for from 1 to 3 weeks

Stage of Reflex Activity. After a variable period of time, depending largely upon the general health of the patient, reflex activity begins to return to the isolated spinal cord below the level of the lesion. The first reflex to appear is usually the sign of Babinski, the extensor response of the great toe to stimulation of the sole of the foot. This reflex is actually a part of the flexor reflex pattern of the lower extremities Both exaggerated extensor and flexor reflex patterns are usually present with lesions of the descending motor pathways They vary in intensity and in relation to each other If the lesion lies above the pons the extensor reflexes usually predominate If the lesion is in the spinal cord the flexor reflexes are usually more prominent than when the lesion lies at higher levels and they may exceed the extensor reflexes in intensity However, this balance between extensor and flexor reflexes fluctuates from time to time in any patient and is quite variable from one patient to another After the sign of Babinski has become elicitable other flexor reflexes, dorsiflexion of the foot, flexion of the knee and hip gradually become more marked and more easily elicited At first they are usually seen only with stimuli which except for the interruption of the pain pathways in the spinal cord would be painful, i e , nociceptive stimuli Later less intense stimuli such as passive flexion of the toes or mere touching of the foot or leg may be sufficient to provoke a violent flexion of the leg When this stage is reached the patient usually has a *paraplegia in flexion* The extensor reflexes begin to return after variable periods At first the only demonstrable reflex of this type may be the patellar tendon reflex (knee jerk) Later the Achilles tendon reflex (ankle jerk) will return, ankle and patellar clonus may be elicited At times the patient may develop severe extensor spasms and the muscles may be involved by severe clonic contractions with little or no external stimulation At other times the extremities may lie quietly without either extensor or flexor reflexes causing any striking disturbances Elicitation of the flexor reflexes will immediately result in a subsidence of ankle clonus or other manifestations of the extensor reflexes, and vice versa This inhibition of the one when the other is produced is due to reciprocal innervation On occasion elicitation of the flexor reflexes will be associated with evacuation of the bowel and bladder However, reflex or automatic evacuation of the bowel and bladder need not be associated with a violent flexion of both lower extremities Such reflex evacuation may result from distention of the bladder or rectum as the case may be, or may be induced by the patient He may produce emptying of the bladder by stimulating the skin or the inner aspect of the upper thigh or reflex defecation by stimulating the rectal mucosa at and just above the anal ring These reflexes are often used to great advantage by the paraplegic patient The time of

development of these various reflexes and their vigor depend in large measure upon the condition of the patient and his paralyzed extremities A poor state of nutrition or the presence of infection in the urinary tract or in decubitus ulcers, the development of severe muscular wasting or of fibrous changes in the muscles, or about the joints will all mitigate against the development of active reflex activity

INCOMPLETE INTERRUPTION OF THE CORD

A bilateral lesion of gradual onset which impairs the activity of the descending motor pathways usually causes *paraplegia in extension* The muscles are spastic and extensor activity predominates The tendon jerks are exaggerated and patellar and ankle clonus can be readily elicited Paraplegia in extension is more or less comparable to decerebrate extensor rigidity The "extensor" plantar response, which is in reality a part of the flexor reflex pattern, is present, but much less intense than in paraplegia in flexion It is associated with much less contraction in other flexor muscles and may be accompanied by a crossed extensor reflex The mass reflex is absent The abdominal reflexes are lost

The Plantar Reflexes. This is the most appropriate place to consider these and other superficial reflexes

The *normal plantar response* to a light scratch applied to the skin of the sole is plantar flexion of the four outer toes with no movement, or, more usually, plantar flexion of the great toe The center for the reflex lies in the first sacral segment, its physiological significance is unknown With a lesion of the corticospinal fibers from the precentral region to the foot at any level above the first sacral segment, the normal response is replaced by one in which *dorsiflexion* of the great toe and often spreading or fanning of the outer toes occurs This response is called after its discoverer the *sign of Babinski* (Fig 9 134) It is elicited best from the outer border of the sole The upward movement of the great toe is part of a general flexor response homologous with the flexor reflex elicitable from the hind limb of a lower animal (p 9–70) The flexor nature of the reflex is shown by the associated contraction of the hamstrings, i e , semitendinosus, semimembranosus, and biceps femoris, which usually occurs Its flexor nature is also indicated by the fact that an undoubted extensor reflex such as

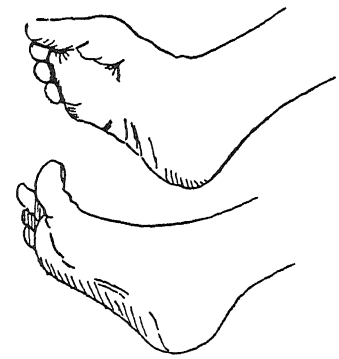

Fig 9 134 *A* Normal response to plantar sensory stimulation *B* Sign of Babinski following similar stimulation

ankle clonus is readily inhibited by evoking the Babinski reaction (reciprocal inhibition)

An "extensor" plantar response is present normally in infants up to the first year or so, i e , to the age of walking, and is then probably due to the undeveloped state of the corticospinal tracts It is also present in normal adults during deep sleep and in the apneic stage of Cheyne-Stokes respiration, being apparently due in the latter instance, to anoxemia of the motor cortex

Other Superficial Reflexes. *1) Oppenheim's reflex* is simply a modified Babinski response, it is associated with the same conditions as the latter and has a similar significance It consists in dorsiflexion of the hallux which results when a firm downward sliding pressure is applied to the skin over the anterior border of the tibia The Gordon, Chaddock, and Gonda reflexes are other modifications of the Babinski response

2) Abdominal reflexes Lightly scratching the skin of the abdomen of a normal person causes a reflex contraction of the abdominal muscles They do not appear until between the 6th and 8th months of age when the infant can sit up unsupported These reflexes are, of course, abolished by any lesion which interrupts afferent conduction from the skin of the abdomen or destroys the anterior horn cells or the motor pathways concerned with the abdominal musculature These reflexes also are often abolished by a lesion which interrupts the corticospinal pathways above the 7th thoracic segment, but they are not permanently abolished by extirpation of the precentral gyrus These confusing facts have thrown se-

is, all types of sensation on the opposite side of the body tend to be lost or grossly affected In addition to the loss or diminution of sensation, lesions of the thalamus are not infrequently associated with spontaneous pain and with marked hypersensitivity which has a very unpleasant quality These manifestations are part of the thalamic syndrome described below and are not well understood

The Thalamic Syndrome of Dejerine and Roussy. This is a characteristic picture occasionally seen in thalamic disease The following are its chief features

1) Asterognosis and sensory ataxia are due to the impairment of cutaneous and kinesthetic senses These and the other effects given below are mainly on the contralateral side of the body

2) There is some loss of tactile and thermal sensations over the body and face, and the threshold for these sensations, and for pain, is frequently raised Sometimes the patient with a thalamic lesion is unable with closed eyes to localize the position of a limb, and must grope in the air in order to find it (*thalamic phantom limb*), or he may have the illusion that the limb is not there at all (*amelognosia*) He also is commonly unable to localize a point which has been stimulated even though he recognizes the stimulus

3) Spontaneous pain occurs in paroxysms and is often excruciating Other stimuli are often associated with an unpleasant sensation Cold in particular may be most disagreeable but light touch may also be unpleasant These spontaneous discomforts and unusual reactions to various stimuli are usually referred to as *thalamic overreaction*

4) Lesions in the thalamus are frequently associated with various abnormal involuntary movements Choreoathetosis and intention tremor are the more common It is believed that choreoathetosis results from the involvement of the projection system from the basal ganglia to the anterior part of the ventrolateral nucleus of the thalamus, whereas an intention tremor arises when the pathway from the dentate nucleus of the cerebellum and the red nucleus is damaged at its point of termination in the posterior part of the ventrolateral nucleus This nucleus in turn projects to the precentral motor cortex and it is thought possible that these abnormal involuntary movements arise because regulating impulses from the thalamus to the motor cortex have been destroyed (Bucy, 1942) Furthermore, such lesions commonly give rise to an abnormal posture of the extended hand known as the "*thalamic hand*" This is characterized by a moderate flexion of the wrist and a hyperextension of the fingers The same posture of the outstretched hand is also referred to by some as the "athetoid hand"

5) Hemiparesis and defects in the visual fields which may be seen in some patients exhibiting the thalamic syndrome are not the result of thalamic involvement but are due to damage to the neighboring internal capsule and geniculocalcarine pathways

DISORDERS OF THE HYPOTHALAMUS

The effects which may result from lesions (e g , tumors, encephalitis, etc) involving the hypothalamic region fall into the following groups *a*) disturbances in regulation of energy exchange or of water balance, *b*) disorders of sleep, drowsiness, somnolence, and less commonly, abnormal wakefulness, or reversal of the sleep rhythm, *c*) emotional manifestations, laughing, crying, or a state resembling "sham rage" in animals, *d*) phenomena attributable to sympathetic or parasympathetic stimulation, and *e*) disorders of the sexual functions and other signs of failure of normal hypothalamic control of the anterior lobe of the pituitary gland

Any one of the foregoing groups of effects may dominate the clinical condition to give rise to one or other of the following syndromes *a*) diabetes insipidus (see p 9–135), *b*) obesity with genital dystrophy (sect 7, chap 2, and *c*) narcolepsy

Narcolepsy. This is the term applied to a disturbance in the sleep mechanism in which sudden attacks of an irresistible desire for sleep occur during the daytime The duration of the attacks, which resemble normal sleep, is quite brief—from a few seconds to 20 min or so The condition may be a sequel to influenza or to epidemic encephalitis involving the hypothalamus or may result from a tumor or injury in this region In other instances the condition appears without known cause (idiopathic narcolepsy) Although evidence is not conclusive, it is very likely that in these latter, also, disordered hypothalamic function is responsible, for other features, e g , obesity, polyuria, or impairment of the sexual functions, pointing to an abnormality of this region are frequently present

Cataplexy[1] is the term given to a condition allied to, and very frequently associated with narcolepsy in which the patient as a result of some emotion—amusement, anger, fear, embarrassment, or surprise—is seized with complete muscular relaxation and weakness The attack is brief, leasing for a few seconds, or for a minute or two at the most Consciousness is not lost but the muscles are completely toneless and powerless for the time, and if the attack supervenes while the subject is standing his knees fail him and he sinks to the ground The deep reflexes are lost Mirth is especially likely to precipitate a cataplectic attack Though narcolepsy occurs without cataplexy the converse is extremely rare This association of the two conditions at once suggests a common pathogenesis, but the muscular atonicity characterizing the cataplectic attack cannot be explained upon any physiological basis

MANIFESTATIONS OF CEREBELLAR DISEASE

The signs of cerebellar disease are much more pronounced in acute lesions, e g , abscess, hemorrhage, or trauma, then in those, e g , tumor, which develop more gradually In slowly developing lesions or after the subsidence of acute cerebellar disease a certain degree of compensation for the cerebellar defect always occurs The majority of the signs of cerebellar disease are the result fundamentally of asynergia of the voluntary muscles

The more conspicuous signs of a cerebellar lesion are *1) Hypotonia of the skeletal muscles 2) Asthenia*, easy fatigability and slowness of movement *3) Dysmetria*, which is the inability to adjust the strength of a contraction required to accomplish a given act For example, when the subject is asked to touch a point with his finger he overshoots the mark, or, less usually, fails to reach it *4) Rebound phenomenon* If the patient is asked to attempt a movement against a resistance which is then suddenly removed, the limb moves forcibly in the direction toward which the effort was made For example, if the observer holds the wrist of the patient, then asks him to bend the elbow, and while he is making the effort, the forearm is suddenly released, flexion of the arm occurs with an unusual degree of force This rebound phenomenon can be attributed to the absence of the "braking" action of the antagonistic muscles 5) *Adiadochokinesis* (a = privative, diadocho = succession, kinesis = movement) is the name given by Babinski to the inability to execute alternating movements rapidly, e g , pronation and supination of the forearm, or flexion and extension of the fingers *6) Deviation of the eyes, and nystagmus 7) Gait* may be staggering, reeling or lurching, often with ataxia of the limbs The *attitude* of the body may be abnormal, the trunk being flexed toward the side of the lesion and the head rotated with the chin pointing toward the sound side *8) Disturbances of speech*, which may be drawling, scanning, sing-song, or explosive in character *9) Intention tremor* that makes it impossible for the patient to perform normal voluntary movements Most of these symptoms have been considered in chapter 5 in connection with normal cerebellar function

DISEASES OF THE BASAL GANGLIA

As noted in chapter 5, the chief clinical features of disease of the basal ganglia are *a)* muscular rigidity resulting in disturbances of posture and movement, *b)* involuntary movements, e g , tremor, athetosis, chorea, *c)* a loss of automatic and associated movements such as those of emotional expression, the swinging of the arms of walking, etc , and *d)* absence of a paralysis of voluntary movement, although it may be distinctly impaired by one of all of the other manifestations The basal ganglia are particularly susceptible to certain toxins (e g , carbon disulfide), to anoxia, and to certain encephalitic processes The following are some of the syndromes met with *a)* Progressive hepatolenticular degeneration, *b)* parkinsonism —paralysis agitans, *c)* chorea, *d)* athetosis

Progressive hepatolenticular degeneration (Wilson's disease). This was described by Wilson in 1912 It is a progressive disease that is familial, characterized by a complex deficiency in copper transport in the blood The symptoms are caused by deposition of copper in the lentiform nucleus The following are its chief features

1) Muscular rigidity is widespread and progressive, it involves face, trunk, and limbs Flexors as well as extensors are affected, but the former more conspicuously than the latter The hypertonus offers a "lead-pipelike" resist-

[1] This should not be confused with catalepsy, an entirely different condition

ance to passive movement and results in slowness and difficulty of movement Eventually, contractures occur and the patient is rendered almost immobile The rigidity of the facial muscles gives a fixed, blank expression The mouth is sometimes held widely open, the smile or laugh is peculiarly stiff and vacuous The hypertonus of the muscles of articulation and deglutition leads to dysarthria (p 9–160) and dysphagia The rigidity is temporarily abolished by the injection of novocaine into the muscles

2) *Involuntary movements* These consist chiefly of tremor (about 6 oscillations/sec) which is increased by excitement or any attempt at voluntary movement, sometimes athetoid movements occur (see below)

3) *Reflexes are normal* There are no sensory changes and although the muscles often show some weakness and are easily fatigued there is no actual paralysis

4) *Cirrhosis (multilobular) of the liver* is found at autopsy, but during life there may be no signs of liver disease In some instances, however, symptoms pointing to the liver precede the nervous manifestations

5) *Emotionalism* Involuntary laughing or crying, and some mental deterioration

6) *Greenish brown pigmentation of the cornea* (in Descemet's membrane) occurs in most cases

Degeneration of the cells of the putamen and globus pallidus, sometimes with cavitation, is found at autopsy The caudate nucleus is affected to a much less degree

The Parkinsonian Syndrome. The principal features of this syndrome are the following *a)* A *coarse tremor* involving head and limbs The hand may show "pill-rolling" movements, i e , rhythmical movements of thumb upon the first two fingers Alternating movements of flexion and extension at the wrist, or of supination and pronation of the forearm, are frequently present When the limb is engaged in some voluntary act the movements often temporarily disappear in that limb The tremor becomes more pronounced during emotional excitement or when the patient is under a nervous strain It disappears during sleep The tremor also disappears on the paralyzed side if hemiplegia supervenes Ablation of the motor area of the cortex, or section of the lateral corticospinal tracts also abolishes it in the related extremities It therefore seems to be dependent upon an intact pyramidal tract However, this has been questioned by some surgeons who believe they have abolished the tremor by producing lesions in the globus pallidus, the thalamus, or the midbrain *b) Muscular rigidity* which leads to slowness and stiffness of movement The rigidity is different both in its quality and distribution from that characteristic of the decerebrate animal or of the hemiplegic patient Flexors and extensor muscles are affected about equally, and the resistance of a limb to passive movements has been described as resembling cogwheels moving slowly upon one another, as though groups of muscles gave way in succession to the stretching force This cogwheel phenomenon is undoubtedly merely a manifestation of the rhythmical innervation of the involved muscles which also gives rise to the tremor The upper limbs are held in characteristic attitudes of adduction at the shoulders, flexion at the elbows, flexion or slight extension at the wrists, flexion at the interphalangeal joints *c)* The *gait* is slow and shuffling with short steps, or it may be "festinating" in character, i e , the patient is bent forward and hastens along with short quick steps as though trying to "catch up to his center of gravity" and prevent his falling When pushed forward or backward he cannot stop quickly but moves by a series of small rapidly repeated steps in the direction in which he is pushed *Propulsion* and *retropulsion* are the respective terms applied to these forward and backward movements There is no true paralysis, the reflexes and sensation are unaffected *d)* One of the most constant manifestations of parkinsonism is the *loss of* certain automatic and *associated movements* As a result the patient does not swing his arms as he walks, the typical facial expressions of various emotions are decreased or absent and the face is said to be masklike Because the many little movements of the body which characterize normal human activity are absent the patient stands rigidly and without moving, "like a statue "

The pathogenesis of these symptoms and their relief following administration of dihydroxyphenylalanine (dopa) have been discussed in chapter 5, pp 9–110–9–112

Chorea. There are two principal forms of this condition

1) Sydenham's Chorea (or St Vitus's dance) is one of the manifestations of rheumatic fever

Its chief feature is involuntary jerky movements, semipurposeful in character, involving the muscles of the limbs and face Facial grimacing, an inability to remain quiet, the frequent dropping of objects from the hands, and the inability to maintain sustained muscular contractions characterize the disease

Sydenham's chorea may be bilateral or unilateral Death is rare and there is consequently uncertainty concerning its neuropathology In those few cases where examinations have been made the lesions have been multiple and diffuse, involving both cerebral cortex and subcortical structures

2) *Huntington's Chorea* is a rare familial disease which results in severe disability and ultimately terminates fatally It is transmitted as a dominant characteristic but the onset is usually late in the fourth decade of life Pathologically one finds severe degeneration and atrophy of the caudate and lenticular nuclei The small cells of the caudate nucleus and putamen are particularly affected However, the large cells are not entirely spared and changes are seen in the globus pallidus and cerebral cortex The disease is characterized by facial grimacing, jerky gesticulating movements of the upper extremities and a lurching, uncertain gait Speech is dysarthric The motor disturbances steadily increase until the patient is incapacitated There is mental deterioration with irritability and occasional homicidal and suicidal tendencies

Athetosis is a form of abnormal involuntary movements beginning most often in childhood It is associated with damage to the basal ganglia, particularly the caudate nucleus and the putamen This damage may result from asphyxia or injury at birth, or from injury or encephalitis subsequently Pure athetosis consists of slow, writhing, twisting movements of the involved extremities and the face In many cases there are also quicker, jerky involuntary movements and the condition is then termed *choreoathetosis* As with most other abnormal involuntary movements these are present during all waking hours and are absent during sleep They are aggravated by nervous tension and are diminished or abolished by the ingestion of alcohol In many patients choreoathetoid movements are unilateral and are associated with a hemiparesis on the same side Unilateral choreoathetosis can be abolished by removal of the contralateral precentral motor cortex (areas 4 and 6) They can also be diminished by section of the central portion of the contralateral cerebral peduncle which contains the corticospinal fibers from the precentral gyrus A few cases have been reported in which the movements have been decreased after surgical lesions have been placed in the region of the internal segment of the globus pallidus or the ansa lenticularis

DISSEMINATED (MULTIPLE) SCLEROSIS

This is a chronic disease of the nervous system characterized anatomically by the occurrence of small patches of demyelination followed by overgrowth of glial tissue throughout the white substance of the brain (especially in the regions beneath the lateral ventricles), and spinal cord The lesions in the cord are most numerous in the corticospinal tracts and in the posterior columns Clinically, the disease is marked by an insidious onset, irregular course, with remissions and relapses of unpredictable duration, and a great variability of signs and symptoms between individual cases Progressive spastic weakness of the muscles of the legs, with increased tendon jerks, "extensor" plantar response (Babinski) and loss of abdominal reflexes, is a common manifestation of this disease Many patients also complain of paresthesias and have a loss of vibration and muscle senses from lesions in the posterior columns The loss of tactile and pain and thermal sensibilities is seldom striking and rarely of an enduring nature Impairment of vision, or even blindness, may result from involvement of the optic nerve, chiasma, or tract Nystagmus, slurring of speech, and intention tremor, once regarded as diagnostic of the disease, appear late if at all and are manifestations of involvement of cerebellar pathways

Epilepsy

Epilepsy is a disorder arising as the result of an abnormal and severe discharge of nerve impulses from some part of the central nervous system, usually the cerebral cortex

TYPES OF SEIZURES

Epilepsy may be generalized, involving the entire organism, or localized Generalized seizures are of three types, grand mal, petit mal, and psychomotor

In *grand mal* there is an abrupt loss of consciousness and a generalized convulsion Two stages of the attack or seizure are recognized In the first or *tonic stage* the muscles contract tonically, the spasms often twisting the facial features and holding the head and limbs in distorted positions The arms are most commonly flexed and the lower limbs rigidly extended After a few seconds the tonic spasm gives place to jerking movements, often violent, of the limbs, face, and muscles of mastication This is spoken of as the *clonic stage* Either during this stage or in the tonic stage the tongue may be bitten Before the onset of the convulsion a large proportion of epileptics receive a warning in the form of a sensation or hallucination, the character of which varies in individual cases The warning sensation or *aura*, as it is called, may be auditory (voices, music) visual (flashes of light, sparks) olfactory, gustatory, cutaneous, visceral or vasomotor, equilibratory, or anesthetic, i e , a numbness in some part of the body Turning of the head and trunk to one side and deviation of the eyes are commonly observed The patient sometimes utters a cry or scream—the epileptic cry—just before consciousness is lost After the convulsion the subject remains for a time in a stupor Sometimes a number of convulsive seizures occur in rapid succession, the patient failing to regain consciousness in the intervals between them This very serious condition is called *status epilepticus*

Minor seizures known as *petit mal* are characterized by brief periods during which the patient loses contact with his environment He stares into space There are no convulsive movements

A third form known as *psychomotor* epilepsy is marked by automatic movements, such as smacking of the lips, chewing, together with a clouded, "dreamy" feeling of unreality, or of having seen or heard before some sight or auditory impression which is actually happening at the moment (*déjà vu* or *déja entendu* phenomenon, respectively) Or there may be a confused mental state persisting for a minute or two, or for a longer period. During this time the patient may perform automatic acts of which he is quite unaware and does not remember Generalized convulsions do not occur nor does the subject fall to the ground during the psychomotor seizure, but patients who have such seizures may also suffer from generalized convulsions Psychomotor seizures are most commonly due to disturbances in the temporal lobe

Localized epilepsy may occur in several different forms, these are often referred to as *jacksonian epilepsy* They signify an abnormality in a particular part of the brain Thus, motor Jacksonian seizures are indicative of a disturbance in the precentral motor cortex, hallucinations of taste and smell are indicative of an abnormal nervous discharge from the uncus on the medial surface of the temporal lobe, sensory jacksonian seizures indicate disease in the parietal region, etc

Motor jacksonian seizures commonly begin by a turning of the head and eyes toward the side opposite the cortical lesion if it is located in the anterior part of the precentral motor cortex, or by a twitching of the foot or leg if it is in the upper part of the precentral region Such attacks may also begin with a twitching of a finger, or of the hand or the face depending upon the seat of the irritation in the cortex which initiates the attack These convulsions may remain localized to the part of the body in which they start or they may spread by a steady "march" to neighboring parts as portions of the cortex lying near to the original focus become involved in the irritative process The spreading convulsion may cease after extending to all of one extremity or to one side of the body or it may continue until a generalized convulsion has occurred

Such focal or localized convulsive seizures or seizures with localized onsets may develop as the result of many different kinds of disease processes in the brain Tumors, abscesses, traumatic scars, vascular abnormalities are among the more common processes found to be responsible for such attacks It must be noted that not all patients who have such disease processes suffer from epileptic attacks and that even in those patients who do have them the attacks occur at relatively infrequent intervals although the disease process is constantly present It is thus obvious that some other process, neurological or metabolic, is essential to the development of such seizures The tumor or scar alone is not enough

Idiopathic or cryptogenic epilepsy. Epilepsy which cannot be explained by the presence of a demonstrable lesion of the brain is called idiopathic or cryptogenic Though many theories have been advanced, the cause of this type of

the disease remains obscure There is a tendency today to look upon epilepsy as a symptom, or rather a group of symptoms common to several rather than to a single primary pathological state Convulsions, whose features are indistinguishable from those of the epileptic seizure, occur in a number of conditions In animals convulsions may be produced by injections of absinthe or caffeine Hypocalcemia, hypoglycemia, cerebral edema, or anemia and other states may be accompanied by generalized convulsions of an epileptiform character

ORIGIN OF SEIZURES

With regard to the neural mechanism through which the fits are produced, some authorities have thought that all convulsions are the result of increased excitability of the cortex and, therefore, comparable in their mode of production to those of the Jacksonian type, or to those produced by experimental stimulation of the cortex Others view the convulsions as a release phenomenon due to the inhibition of cortical areas which normally exert a controlling influence upon lower motor centers, e g , weakening of suppressor action Finally, there is the view of Penfield and Jasper (1954) that the primary disturbance in idiopathic epilepsy has its origin in a subcortical mechanism

The close correspondence between the convulsive seizure as seen in focal epilepsy or after artificial stimulation of the cortex, and the fits of idiopathic epilepsy appears to support the first alternative as a cause of the generalized seizure known as grand mal However, the *primary* disturbance responsible for the cortical discharge in idiopathic epilepsy probably lies outside the cortex Evidence for a subcortical origin of petit mal attacks is provided by electroencephalographic studies During such an attack, electrical potentials of the wave-spike type appear synchronously over prefrontal areas as well as from other widely separated cortical areas This suggests that the cortical discharges are initiated in a common subcortical region (centrencephalic system) connected with extensive areas of the cortex

The nature of the underlying bodily state responsible for the convulsive seizures of idiopathic epilepsy are unknown There are a number of drugs, e g , metrazol, which are capable of inducing convulsions, and several others, e g , phenobarbital and tridione, which are anticonvulsive Susceptibility to an epileptic seizure is influenced by several physiological and biochemical factors which are given in Table 9 7, but they do not bear a specific relationship to the cause of idiopathic epilepsy, but merely affect the tendency to convulsive seizures of any kind

Table 9 7
Summary of conditions which tend to predispose to or to prevent epileptic seizures

Condition	Prevents Seizures	Precipitates Seizures
Oxygen	Rich supply	Poor supply
Acid-base equilibrium	Acidosis Ingestion of acids or acid-forming salts Breathing CO_2	Alkalosis Hyperpnea—"blowing off" CO_2
Water balance	Dehydration	Edema
Serum calcium	Increase	Decrease
Blood glucose	Normal level	Decrease (hypoglycemia)
Body temperature		Increase

The view that the actual seizure was initiated by cerebral ischemia resulting from a spasm of the cortical vessels has not been sustained The blood flow through the brain of epileptics and the oxygen consumption have been found to be no different from those of nonepileptics In focal epilepsy, however, local ischemia may play a part Nevertheless, biochemical studies of such epileptogenic areas have not revealed any important abnormality, and the pH of the extracellular fluid shows no change from the normal, or a slight rise

The induction of a dehydrated state of acidosis (by means of a ketogenic diet) has been employed to reduce the susceptibility of epileptics to seizures but not very effectively, and pitressin combined with an increase in the water intake is used as a test (*water-pitressin test*) in diagnosis But in only about 30% of epileptics is a seizure precipitated, so a negative result does not exclude epilepsy

INDEX

To state the obvious, this index covers all nine sections of BEST & TAYLOR'S PHYSIOLOGICAL BASIS OF MEDICAL PRACTICE, 9th ed What is not so obvious is the reason for inclusion of the complete index with each of the sectional print-outs The latter strategy will not only lead the reader to information in the print-out, but will also point out related and additional information in the other print-outs (or in the book itself)

α Adrenergic receptors
general properties, 9-64
mechanisms of action, 7-73
α Cells, pancreatic islets, 7-77
α Helix of protein, 1-124
α Rhythm, EEG, 9-107
α, β, δ, Chains of hemoglobin, 4-42
A band, myocardial sarcomere, 3-30 ff
A blood group, subgroups, 4-50
A nerve fibers, properties of, 1-42
Abdominal muscles in respiration, 6-49
Abdominal reflexes, 9 164
Abducens nerve (VI), 9 32
Aberration in eye, 8-67
ABO system of blood groups, 4 48
inheritance of, 4-50
Absolute refractory period
of muscle, 1 80
of nerve, 1 45
Absolute threshold, auditory, 8-31
Absorption, intestinal, 2-83 ff
of carbohydrate, 2 86
of electrolytes, 2 85
of fat, 2 91
of protein and amino acids, 2 89
of vitamins, 2-93
transamination during, 2 90
Absorption of air, 6 75
Absorption of water, 2-84
Acceleransstuffe, 9-60
Acceleration
angular, 8-41
coriolis, 8 54
Accessory muscles of respiration, 6-30
Accessory nerve, spinal, 9 38
Acclimatization to altitude, 6-66
Accommodation in bladder wall, 5 54
Accomodation in eye, 8-72
in depth perception, 8-118
Accommodation in nerve, 1-37
and activity of ion pumps, 1-50
Accommodation vs setpoint, 9-19
Acetate in lipid syathesis, 7-126
Acetazolamide vs carbonic anhydrase, 6-17
Acetoacetate, ketone body, 7-139
Acetone, ketone body, 7-139
Acetyl CoA
in control of ketogenesis, 7-139
in lipid synthesis, 7-124
significance in lipogenesis, 7-141
Acetyl CoA carboxylase, in control of lipogenesis, 7-142
Acetylcholine
as autonomic transmitter, 9-60
as neuromuscular transmitter, 1-57
as *Vagusstuffe*, 9-60
in control of muscle, 9-66
increase in coronary blood flow, 3-138
summary of transmitter sites, 1-58
Acetylcholine action
in adrenal medulla, 9-61
on epinephrine secretion, 7-72
on food intake, 2-3
on muscle membrane potential, 1-89
Acetylcholinesterase, in autonomic system, 9-61
Acetylene, arteriovenous, measurement of cardiac output, 3-159
Achalasia, 9-93
Achalasia and pain, 2-13
Acid-base balance, 5-27 ff
disturbed in dehydration, 4-117
disturbed in uremia, 5 46
various disturbances, 4-110
Acid-base properties of amino acids, 1-116
Acid hemolysis of RBC, 4-58
Acidemia, 4-107
Acidification of urine, 5 29 ff
Acidity and gastric emptying, 2-109
Acidity of gastric juice, 2-47
Acidophils of anterior pituitary gland, 7 8
Acidosis
as cause of dyspnea, 6 62
characteristics, 4 107
clinical types, 4-108
of renal dysfunction, 5 45
Acidosis, metabolic
causes, characteristics 4-108
in insulin deficiency, 7-87
Acidosis, respiratory, 4 107
Acromegaly, 7-143
ACTH (adrenocorticotrophic hormone)
amino acid sequence, 7-60
and aldosterone secretion, 7-63
and glucocorticoid synthesis, 7-60
ectopic production of, 7-64
measurement of, 7 61
ACTH-RF, 7 20
ACTH secretion
control of, 7-61
feedback control loops, 7-15
ACTH vs MSH, 7-61
Actin
arrangement in sarcomere, 3-30
concentration in myocardium, 3-32
interaction with tropomyosin and troponin, 3-38
Actin filaments, 1-62
Actin in muscle, 1-65
Actinins of muscle, 1-70
Actinomycin D
inhibits mRNA synthesis, 7 149
mechanism of inhibition of RNA synthesis, 1-171
Action currents in nerve, 1-43
Action potential, 1-37
history of theories, 1-45
modern concepts of, 1-46 ff
of auditory nerve fibers, 8-23
of skeletal muscle, 1-89
recording techniques, 9-10
sequence of ionic events, 1-48
technique for recording, 1-40
Action potential, compound
in sensory nerve, 8-8
of mixed nerve, 1-41
Action vs. resting potentials, 1-34
Activating mechanism, reticular, 9-140
Activation of amino acids, 1-173
Activation of EEG, 9-137
Active points in muscle, 1-85
Active state in muscle
effect on properties of muscle, 1-87
properties of, 1-82
Active transport, 1-21
Active transport in glands
bile secretion, 2-72
of I in thyroid, 7-30
saliva secretion, 2-21
Active transport in gut
amino acids, 2 89
electrolytes, 2-85
sugars, 2-87
Active transport in kidney
by renal tubules, 5-8 ff
of amino acids, 5-12
of glucose, 5-9 ff
of phosphate, 5-13
of sulfate, 5-13
of uric acid, 5-13
Active transport of cations, 1-5
energy cost in nerve, 1-52
Active vs inactive state of nerve, 1-51
Activity, suppressed by hypothalamus, 9-142
Actomyosin, 3 33
Acute renal failure, 5 43
Adaptation
in olfaction, 8-140
in vestibular system, 8-54
of nystagmus, 8-55
of touch sensation, 8-150
of urinary bladder, 5-53
renal, to acidosis, 5-32
Adaptation vs setpoint, 9-19
Addison's anemia, 4-33
Addison's disease
and renal dysfunction, 5 47
clinical features, 7-63
Adenine, 1-142
Adenohypophysis, 7-8 ff
actions of growth hormone, 7 143
control of hormone synthesis, 7-22
control of Leydig cells, 7-95
control of testis tubules, 7-99
control of thyroid function, 7-35
cytophysiology of, 7-8
embryology of, 7-24
hypothalamic connections, 9-41
listing of hormones, 7-8
mechanisms of control of, 7-8
mechanisms of hormone release, 7-21
neurohumoral control of, 7-13 ff
ADP (adenosine diphosphate), cardiac muscle contraction, 3-40
Adenosine triphosphate (ATP)
and fat absorption, 2-91
as purine derivative, 1-142
with G-actin, 1-66
Adenyl cyclase
activated by catecholamines, 7-73
in second messenger theory, 7-5
relation to lipolysis, 7-128

Adenylic acid,
biosynthesis of, 1-149
Adequate stimulus, 8-1
Adipocyte, 7-123
Adipose tissue, metabolism in, 7-123
Adipsia, hypothalamic, 9-126
Adolescence
and growth hormone, 7 143
growth of muscles, 7-146
Adrenal cortex, 7-50 ff
and renal dysfunction, 5-47
and water intoxication, 4-117
regeneration of, 7-50
Adrenal hormones (see name or type of hormone)
Adrenal medulla, 7-70 ff
disorders of, 7-75
Adrenal medullary catecholamines, regulation of heart, 3-115
Adrenal steroids
affect secretion of H^+, 5-34
affect sodium excretion, 5-25
in edema of cardiac failure, 5-45
Adrenaline (see Epinephrine)
Adrenergic nerves to gut, 2 8
Adrenergic system, 9-53
Adrenergic transmission, 9-62
Adrenochrome, 9-63
Adrenocortical dysfunction, 7-63
Adrenocortical tumors, 7-64
Adrenocorticotrophic hormone (see ACTH)
Aerobic metabolism of nerve, 1-50
Aeroembolism, 6-68
Afferent fiber types, 9-74
Afferent visceral nerves, 9-54
Afibrinogenemia, 4-80
After discharge, 9-72
After-image, colored, 8-114
Agglutination of RBC
by polyelectrolytes, 4-58
relation to blood groups, 4-48
Aggregation of ribosomes, 7-152
Aging and hearing, 8-35
Aging of lens, 8-68
Agnosia, 9-150
Agraphia, 9-151
Aids to hearing, 8 39
Air
absorption of, 6-75
composition, 6-5
Air conduction tests, 8-37
Airplane ascents, hypoxia in, 6-66
Airway during swallowing, 2-97
Airway resistance, 6-35
Alanine cycle, 7-136
Albumin of serum, 4-4
bilirubin binding, 2-65
binding to testosterone, 7-97
Albuminuria (see Proteinuria)
Aldolase activity, 7-127
Aldosterone
and renal tubular function, 7-59
biosynthesis of, 7-51
controls sodium excretion, 5-25
excess secretion of, 7-70
hypersecretion causes edema, 5-47
metabolic effects of, 7-59
metabolism of, 7-53
rate of renal excretion, 7-56
rate of secretion, 7-56
Aldosterone synthesis, regulation of, 7-62
Alkalemia, 4-107
Alkali reserve of plasma, 6-9
changes in dyspnea, 6-62
Alkalosis, 4-107
metabolic, 4-110
respiratory, 4-109
Allantoin from purines, 1-152
Alleles (of genes), 1-136
Allergy and asthma, 6-73
Allograft rejection, 4-99
All-or-none principle
in innervated muscle, 1-44
in nerve, 1-43
in skeletal muscle, 1-81
Allosteric control of enzymes, 7-114
Alloxan diabetes, 7-145
Alveolar air, 6-4, 5
gases of, 6-21
Alveolar air equation, 6-22
Alveolar gas exchange
anatomical shunts, 6-22
physiological shunts, 6-23
Po_2 gradient, 6-13
ventilation-perfusion abnormalities, 6-23
Alveolar vs total ventilation, 6-20
Amacrine cells of retina, 8-75
American population blood groups, 4-49
Aminoaciduria, 5-46
Aminoacidurias, pathogenesis of, 1-140
Amino acids, essential, 1-129
activation by tRNA, 1-173
active transport in kidney, 5-12
and ribosomal aggregation, 7-152
as precursors of glucose, 7-136
codon assignments for, 1-176
evoke insulin release, 7-79
for gluconeogenesis, 7-134
incorporation into protein, 7-152
intermediary metabolism of, 1-131 ff
intestinal absorption, 2-89
physicochemical properties of, 1-116
sources of renal NH_3, 5-31
summary of metabolic reactions, 1-135
utilization of, 1-129
Amino acid transport
affected by insulin, 7-84
control of entry into cells, 7-151
hormonal control of, 7-148
in plasma, 4-4
transmembrane, 1-139
Amino acids, 1-117
Amino acyl-tRNA, 1-180
p-Aminohippuric acid (PAH)
secretion by kidney, 5-14
tests based on clearance, 5-39
Ammonia
and acidification of urine, 5-31, 32
from deamination processes, 1-134
renal secretion of, 4-106
Amnesia, 9-157
5'-AMP and phosphorylase, 7-118
Amphetamine and food intake, 2-2
Ampulla, vestibular, 8-42
Amylase, pancreatic, 2-52
rate of secretion, 2-58
Amylase, salivary, 2-24
Amyloidosis of kidney, 5-40
Anaerobic muscle, 7-113
Anal orifice, defecation, 2-120
Anal reflex, 9-165
Analogue computation, neural, 9-13
Anaphylactic shock, 6-73
Anarthria, 9-150
Androgen (see also Testosterone)
Androgen action on fetal hypothalamus, 7-93
Androgen biosynthesis, 7-96
Androgen secretion in female, 7-106
Androgens from adrenal cortex, 7-51
Androgens from testis, 7-95
Anelectrotonus
and central computation, 9-13
in stimulation of nerve, 1-39
Anemia, 4-31 ff
absence of dyspnea, 6-61
coronary blood flow in, 3-139
cyanosis in, 6-80
hypoxia in, 6-64
Anemia, genetic, 4-20
Anemia of infants, 4-32
Angiotensin
and aldosterone synthesis, 7-62
controls Na^+ excretion, 5-25
increase in coronary blood flow, 3-139
vasoconstrictor effects of, 3-172
Angiotensin II, induces drinking, 9-126
Angular acceleration, 8-41
Animal vs human sensory studies, 8-4
Ankle jerk reflex, 9-86
Anosmia, 8-141
Anoxemia, 6-63
therapy with O_2, 6-81
Anoxia (see Hypoxia)
Anterior chamber of eye, 8-71
Anterior lobe of cerebellum, 9-43
Anterior lobe of pituitary gland (see also adenohypophysis), 7-8 ff
Anterior roots, spinal, 9 23
Anterior thalamic nuclei, 9-39
Antibiotics vs protein synthesis, 1-181
Antibodies
cellular, 4-90
humoral, 4-90
Antibodies of blood groups, 4-50
Antibodies to insulin, 7-86
Antibody responses, 4-91
Antibody synthesis, 4-98
Anticoagulants, typical, 4-81
Anticodons, 1-177
Antidiuresis, 5-18 ff
Antidiuretic hormone (ADH) (see also Vasopressin)
and renal permeability to water, 5-20
and water excretion, 5-18
control of release of, 9-126
Antidromic excitation, 9-76
Antridromic vs orthodromic stimulation, 1-53
Antigens for histocompatibility, 4-100
Antigens of ABO system, 4-48
Antigens, Rh in blood, 4-52
Antiglobulin test (Coombs), 4-50
Antigravity muscles
reflexes of, 9-69
tone of, 9-89
Antithrombin, 4-78
Antrum of stomach, 2-108
Anuria, 5-43
Aorta
blood flow during cardiac cycle, 3-105
pressure during cardiac cycle, 3-104
Aortic arch, innervation of, 3-177
Aortic body, 6-55
afferents in vagus nerve, 6-48
sensitivity to CO_2, 6-53
Aortic coarctation, cardiac circulatory effects of, 3-138
Aortic depressor nerve, control of blood pressure, 3-176
Aphasia, 9-148
Aplastic anemia, 4-19
Aplysia, conditioning in, 9-156
Apnea after hyperventilation, 6-41
in oxygen therapy, 6-82
Apneusis, 6-42

Apoferritin, 4-39
Apolar properties of protein, 1-126
Appetite, 2-1 ff
Appropriate stimulus, 8-1
Apraxia, 9-150
Aptyalism, 2-30
Aqueous humor, 8-71
Arabinose operon, 1-190
Archipallium, 9-104
Area 4, cerebral cortex, 9-112
Area 4 vs area 6, 9 115
Area 6, cerebral cortex, 9-116
Area 8, cerebral cortex, 9-117
saccadic eye movements from, 8 97
Argentaffin cells, intestinal, 2 80
Argyll-Robertson pupil, 9-166
Arterial pressure pulse, 3-194
Arteriolar nephrosclerosis, 5 41
Arteriosclerosis, in renal disease, 5 41
Artificial respiration, 6-83 ff
ASA 1951 curve (for hearing), 8-31
Ascorbic acid in adrenal cortex, 7 51
Asphyxia, 6-64
Aspirin, antipyretic, 9-136
Assembly of proteins, 1 183
Associated movement, automatic, 9-100
Association cortex, cerebral, 9 111
Astereognosis, 9-150
Asthma
bronchial, 6-72
cardiac, dyspnea in, 6-60
volume-flow relations, 6-34
Astrocytes, 1-31
Astronauts, ventilation of, 6-69
Atelectasis, 6-75
Athetosis, 9-170
ATP (adenosine triphosphate), cardiac muscle contraction, 3 40
ATP in muscle
and energy generation, 1 95
formation of cross-bridges, 1-73
ATPase
in adrenal medulla, 7 72
in membrane transport, 1-5
in slow vs fast muscle, 1 112
Atrial fibrillation, effect on volume output of heart, 3 118
Atrial mechanoreceptors, reflex to abdominal muscles, 6 50
Atrioventricular node, 3 56
block of, cause of arrhythmias, 3 75 ff
impaired conduction, 3-75
transmembrane potential, 3 49
Atrioventricular valves
closure, mechanism of, 3-106
movement during cardiac cycle, 3 105
Atrium, heart
anatomy, 3-25
blood volume in contractures, 3-98
conductance velocity, 3-55
contraction, 3 104
extrasystoles, 3-79
transmembrane potential, 3 48
vascular receptors, 3-186
weight, 3-26
Atropine, effect on gastric secretion, 2-46
Audiogram, von Békésy, 8-37
Audiometric zero curve, 8-31
Audiometry, 8-35
Audiometry for speech, 8-38
Audition (see Hearing)
Auditory cortex, 8-30
Auditory discrimination, 8-30
Auditory hair cells, 8-21
potentials of, 8-19
Auditory nerve, 8-15
Auditory system
course of afferent fibers, 8-25
efferent fibers in, 8 25
information processing, 8-29
lateralization in, 8-26
Auditosensory area, 9-111
Auerbach's plexus, esophageal, 2-103
Auscultatory gap, blood pressure measurements, 3-151
Autoimmune thyroiditis, 7 41
Automatic associated movement, 9-100
Automaticity of respiratory centers, 6-44
Autonomic blockade of gastric secretion, 2 47
Autonomic centers, medullary, 9-65
Autonomic conditioning, 9 146
Autonomic control
of gastric secretion, 2 35
of pancreas, 2-55 ff
of salivary secretion, 2 27
Autonomic nervous system, 9-53 ff
higher controls, 9 64
to digestive tract, 2 8 ff
to salivary glands, 2 19
Autophagia in lysosomes, 1-11
Autoradiography of chromosome, 1 165
Avogadro's law of gases, 6-1
Avoidance conditioning, 9-153
Axon hillock, 1-29
Axon of nerve, 1-30
Axonal transport to neural lobe, 7-24

β Adrenergic receptors, 7-73
in autonomic system, 9-64
β Cell, pancreatic islets, 7 77
defect in diabetes mellitus, 7-87
β-Hydroxybutyrate, 7-139
β Lipoprotein, 2-92
β-Pleated sheet of protein, 1-124
3β-ol Deficiency, 7-69
B nerve fibers, properties of, 1-42
Babinski's sign, 9-164
Balance, glomerulotubular, 5-12
Barany chair, 8-49
in clinical tests, 8-55
Baroreceptors
and vasopressin release, 7-27
influence on respiration, 6-48
reflex to abdominal muscles, 6-50
Barospirator of Thunberg, 6-84
Barr body, sex chromatin, 7-91
Basal ganglia, cerebral, 9-99 ff
anatomy and relations, 9-49 ff
summary of diseases, 9-168
Base composition of DNA, 1-158
Base pairing in DNA, 1-161
Base pairs, models of, 1-152
Base sequence of DNA, 1-161
Basic electrical rhythm, gastric, 2-106
Basic taste sensations, 8-121
Basic visual functions, 8-98 ff
Basilar membrane of cochlea, 8-14
Basophils of anterior pituitary gland, 7-8
Basophils of blood, 4-62
Bat wing capillaries, 4-84
Bayliss mechanism in blood circulation, 3-165
Behavior
after visual deprivation, 8-95
in study of sensation, 8-4
Belching, 2-104
Bell-Magendie law, 9–23
Bell's palsy, 9–37
Bends, 6-68
Bernard, Claude
and salivary secretion, 2-26
milieu interne, 9-58
sucre piqûre, 9-65
Bernstein's theory of action potential, 1-45
Betz cells, 9-27
Bezold-Jarisch reflex, 3-185
Bicarbonate-carbon dioxide ratio
in acidosis, alkalosis, 4-107
normal values, 4-105
Bicarbonate ions
and carbonic acid buffer system, 4-104
and CO_2 transport in plasma, 6-16 ff
and gastric secretion, 2-39
in pancreatic juice, 2-50
rate of pancreatic secretion, 2-58
renal transport, 5-27 ff
Biceps jerk, 9-87
Bile, 2-60 ff
electrolytes in, 2-60
essential for cholesterol absorption, 2-93
in gallbladder, 2-73
miscellaneous constituents, 2-69
osmolarity, 2-61
Bile acids, conjugation of, 2-62
Bile ducts
anatomy of, 2-72
obstruction of, 2-68
pressures inside, 2-75
Bile pigments, 2-64 ff
conjugation of, 2-66
enterohepatic circulation of, 2-68
Bile salts, 2-61 ff
enterohepatic circulation, 2-63
excretion of, 2-64
Bile secretion
cellular mechanisms, 2-71
control of, 2-70
rate of, 2-61
Bilirubin, 2 64
conjugation of, 2-66
from hemoglobin degradation, 4-35
hepatic excretion, 2-67
sites of production, 4 42
Biliverdin, 2-64
Binaural hearing, 8-28
Binaural sound localization, 8-33
Binding assay for nucleotide sequence, 1–176
Binocular retinal disparity, 8-120
Binocular vision, coding in cortex, 8-94
Bioelectricity, principles of, 1-32 ff
Biosynthesis of adrenal hormones, 7-50
Biosynthesis of RNA, 1-169
Biot's breathing, 6-58
Bipolar cells of retina, 8-75
Birth
changes in circulation, 6-76
resuscitation of infant, 6-85
Bitter taste, 8-122
Bladder, urinary, 5-47 ff
electron micrograph of, 1-4
physiological capacity, 5-53
reflexes in spinal shock, 9-163
Bleeding time, 4-78
Blind spot, 8-70
Blocking of thyroid hormone synthesis, 7-32
Blood, 4-1 ff
capillary exchange of, 3-16
rheological properties of, 4-61
vascular beds, patterns of, 3-5
vascular distribution, 3-5

Blood cells
granulocytes, 4 62 ff
in blood stored for transfusion, 4-55
model of origin, 4 11
sites of formation, 4-11
Blood clot retraction, 4-75
Blood clotting, 4-75 ff
abnormalities of, 4-79 ff
enhancement of, 4-82
prevention of, 4-81
Blood components for transfusions, 4-53
Blood constituent (see name of constituent)
Blood creatinine, 5-38
Blood flow
aortic phasic, 3-196
arterial, 3-196 ff
bronchial, 3 205
capillary, 3-198
cerebrum, 3-211 ff
circulation time, 3-162
control of, and regulation, 9-124
cutaneous, and temperature regulation, 9-129
electromagnetic flow meter in measurement of, 3 156
exercise effects on, 3-208
fetal, compared with adult, 3-239
Fick principle in measurement of, 3-158
foot, 3 214
hand, 3-214
indicator dilution principle, 3-161
kidney, 3 160, 3-228 ff
liver, 3-226
lungs, 3-204
measurement of, 3-152 ff
measurement of, to kidney, 5-15
mechanical devices for assistance of, 3-153
mesenteries, 3 224
pendulum flow meters in measurement of, 3-156
perfusion systems for measurement of, 3-153 ff
peripheral arteries, 3 197
phasic, flow meters in measurement of, 3-156
regulation, 3-5
respiratory effects on, 3 207
rotameter measurement of, 3-155
skeletal muscle, 3-217
skin, 3-213 ff
sonar flow meter in measurement of, 3-156
spleen, 3-225
to salivary glands, 2-20
vascular resistance in lungs, 3-205
vasomotor control in lungs, 3-209
velocity, 3-4
venous drainage in measurement of, 3-153
vessel velocity changes, 3-18
visualization of microcirculation, 3-152
Blood gases (see also Carbon dioxide, Oxygen, Carbon monoxide)
measurement of, 6-8 ff
transport of, 6-5 ff
Blood glucose, action of insulin, 7-83
Blood glucose and feeding, 2-4
Blood group antigens, 4-49
Blood groups, 4-48 ff
antibodies of, 4-50
miscellaneous types, 4-53
Blood nonprotein nitrogen, 5-38
Blood platelets, 4-73 ff
in thrombosis, 4-81
Blood pressure
auscultatory measurement of, 3 150 151
autoregulation of, 3-6
average value, according to age, 3-189
cardiac output and, 3-20, 3-192
diastolic, 3-190
digestion and, 3-190
distribution in cardiovascular system, 3 6
effects of pH variation, 3-183
emotions and, 3-190
exercise effects on, 3-190, 3-202 ff
extrinsic control, 3-8
elasticity of vessel walls as determinant of, 3-193
flush method for measurement of, 3-152
gauges for measurement of, 3-149
gradient, species comparison, 3-4
heart pumping action as determinant of, 3-191
human aorta, effect of aging, 3-14
indirect measurement in animals, 3-152
intrinsic control, 3-5
level of critical closure of vessels, 3 194 ff
measurement of, 3-148 ff
microphones in measurement of, 3 152
nonoscillatory, 3-148
peripheral resistance unit, 3 192
postural effects on, 3-190, 3-202 ff
pulmonary vessels, 3-21
pulse detectors in measurement of, 3 152
regulation, 3-5
relation of colloid osmotic pressure and, 3-4
respiratory effects on, 3-302, 3-207
systolic, 3-190
transfer function, 3-8
transfusion effects, 3 18
ultrasound in measurement of, 3 152
vascular peripheral resistance as determinant of, 3-191 ff
vein capacity as determinant of, 3 200
venal caval flow as determinant of, 3-201
ventricular contraction as determinant of, 3-200
viscosity of blood as determinant of, 3-193
Blood pressure, arterial, 3-4, 3-189, 3-194, ff
and chemoreceptive reflexes, 6-55
influence on respiration, 6-49
Blood pressure, arteriolar, 3-15
Blood pressure, capillary, 3-15, 3-198 and glomerular filtration, 5-5
Blood pressure, cardiovascular, 3-2
Blood pressure, venous, 3-17, 3 198 ff
Blood sedimentation, 4-60
Blood supply to kidney, 5-2
Blood transfusion, 4-48 ff
incompatible transfusion, 4-53
Blood urea, 5-36 ff
Blood velocity, measurement of, 3-161 ff
Blood vessels
α-adrenergic receptor vasoconstriction of, 3-171
β-adrenergic receptor vasodilatation of, 3 171
diameters and blood content, 3-13
local vs remote control of vasoconstriction, 3-173 ff
of retina, 8 72
parasympathetic vasodilator fibers, 3-170
reciprocal vasoconstriction reactions, 3 180
reflex vasoconstriction, 3-176
remote vs local control of vasoconstriction, 3-173 ff
smooth muscle constriction of, 3-164
vascular tone, 3-172, 173
vasconstrictor fibers of, 3-166, 3-167
vasodilator fibers of, 3-170
Blood viscosity, 4 60
Blood volume
abnormalities of, 4-119
arterioles, 3-15
capillaries, 3-15
clinical features of changes, 4 120
distribution of, 3 2
dog circulatory system, 3 6
normal values, 4-119
pulmonary vessels, 3-21
regulation, 3 5
transfusion effects, 3-18
varies with ambient temperature, 9-130
veins, 3 17
Blood volume estimations, 4-118 ff
Blood volume regulation, 4 117 ff
Body fluid exchange, 4 113 ff
Body temperature regulation (see Regulation of body temperature)
Body weight, control of, 9 127
Bohr effect on hemoglobin, 4 43
Bohr integration, O_2 diffusing capacity, 6 25
Bolus, swallowing, of, 2-97
Bonds in protein molecules, 1-122
Bone and calcium exchanges, 7 44
Bone conduction tests, 8-37
Bone growth, hormonal control, 7-144
Bone marrow
and hemopoiesis, 4-11
drug effects on, 4-19
forms bile pigments, 2-65
granulocytopoiesis, 4-64
in erythropoiesis, 4-21
lymphocytopoiesis, 4 95
suppressed by drugs, etc , 4 71
Border contrasts, visual, 8-90
Boyle's law of gases, 6-1
Brachium conjunctivum, 9-47
Brachium pontis, 9-47
Bradykinin
and inflammation, 4-64
in saliva, 2-25
vasodilation effect in skeletal muscle, 3-219
Brain
embryology of, 9-20
stimulation of, 9 8
Brainstem
auditory systems of, 8-26
autonomic outflow, 9-57
centers for regulation, 9-125
connections of taste fibers, 8 128
control of respiration, schema, 6-46
neural tracts, 9-24 ff
respiratory centers, 6-42 ff
single vestibular units, 8-58
structure, 9 30
vestibular nuclei, 8-49
Breast development, in pregnancy and lactation, 7-109
Breathing (see also Pulmonary ventilation, Respiration)
abnormal patterns, 6-58
at high pressures, 6-83
changes in pneumonia, 6-71
control of, 6-41 ff
efficiency of, 6-37
mechanics of, 6-28 ff
periodic, 6-58

positive pressure, 6-49
work of, 6-36
Brightness discrimination, 8-99
Brodmann's areas of cerebral cortex, 9-105
Bromide ion in saliva, 2-23
Bromosulphalein
excretion by liver, 2 72
use in measurement of kidney blood flow, 3-160
Bronchioles in asthma, 6-72
Bronchopneumonia, 6-69
Brunner's glands, 2-80
Brush border, intestinal, 2 87
Buffer action and pH of urine, 5-30
Buffer systems for H^+, 4-104 ff
Bulbar facilitatory mechanism, 9 93
Bulbar inhibitory mechanism, 9-93

Clot dissolution, 4-77
Clot retraction time, 4-78
Clotting mechanism, 4-75 ff
Clothing and temperature regulation, 9-130
CNS control of respiration, 6-52 ff
CNS control of urinary tract, 5-51
Coagulation factors in lymph, 4-85
Coagulation of blood (see also Blood clothing), 4-75 ff
Coagulation time, 4-78
Cobalt in vitamin B_{12}, 4-38
Cochlea, 8-14 ff
electrical potentials in, 8-22
innervation of, 8-23
microscopic anatomy, 8-16
Cochlea vs vestibular system, 8-15
Cochlear efferent system, 8-25
Cochlear microphonic potentials, 8-20
Cochlear nuclei in hearing, 8-26
Code, genetic, 1-175 ff
Coding, neural, 9-12
for color vision, 8-91
of sensory response, 8-9
of sensory signals, 8-3
Codon-anticodon interaction, 1-177
Codons for protein synthesis, 1-175
Coefficient of O_2 utilization, 6-14
Coenzyme A from pyruvate oxidation, 1-103
Cold agglutinin and hemoglobinuria, 4-59
Cold receptors, 8-153
Colitis, ulcerative, 2-117
Colligative properties of water, 5-17
Colloid of thyroid gland, 7-33
Colon, motility of, 2-117
Colonic motility, abnormalities, 2-119
Colonic secretion, 2-82
Color anomaly, 8-117
Color blindness, 8-114 ff
Color discrimination, 8-113
Color vision, 8-113 ff
and stimulus wavelength, 8-91
coding in cortical units, 8-94
coding in lateral geniculate body, 8-91
sensitivity of receptors, 8-83
Columns of spinal cord, 9-21 ff
Commissures of brain, 9-119
Commissures of spinal cord, 9-22
Common bile duct, 2-72
Communication and speech, 9-147
Comparative physiology
of blood, 4-1
of calcitonin, 7-47
of cerebellum, 9-97
of cerebral cortex, 9-88
of deficits from cerebral cortex, 9-113
of insulin, 7-76
of membranes, 1-26
of releasing factors, 7-20
of sensory processes, 8-4
of temperature regulation, 9-128
of velocity of nerve impulse, 1-43
Compartment analysis
for erythropoiesis, 4-22
in hemopoiesis, 4-16
of granulocytopoiesis, 4-65
Compensation for acid-base disturbances, 4-107 ff
Compensation, intracodon, 1-185

Competition in carrier transport, 1-20
Competition of sugars for carrier, 7-115
Compliance of lung, 6-31
Compound action potential
in sensory nerve 8-8
of mixed nerve, 1-41
Compromise in control systems, 9-17
Computer analysis of sensation, 8-6
Computer for clinical diagnosis, 4-112
Computer print out, H^+ disturbance, 4-111
Concentration gradient and transmembrane movement, 1-18
Concentration potentials, 1-33
Concentration test, urine, 5-39
Conditioned reflexes, 9-151 ff
Conditioned secretion of saliva, 2-26
Conditioning, autonomic, 9-156
Conditioning, classical, 9-151
electrical recordings 9-151
Conditioning, instrumental, 9-153
Conditioning, mechanism of, 9-156
Conditioning, neuronal, 9-156
Conduction deafness, 8-34
Conduction velocity vs fiber size, 1-42
Cone pigments and color vision, 8-91
Cones vs rods
distribution of, 8-69
in dark adaptation, 8-101
Conformation of protein, 1-127
Congenital adrenal hyperplasia, 7-66
Congenital cardiac defects, 6-77
Congenital neutropenia, 4-72
Conjugation of bacteria, 1-163
Conjugation of bile pigments, 2-66
Connectors, neural, 9-2
Consciousness of rotation, 8-53
Consciousness of sensation, 8-2
Constipation, 2-120
Continence of urine, 5-54
Contraction of muscle, 1-61 ff
isometric, 1-82
isotonic, 1-79
Control
of energy balance, 9-127
of enzymes in muscle, 7-114
of exocrine glands, 9-53 ff
of intestinal motility, 2-114
of skeletal muscle, 9-66 ff
of smooth muscle, 9-53 ff
of water balance, 9-125
Control, endocrine
of cell size and number, 7-146
of gluconeogenesis, 7-137
of lipolysis, 7-130
of protein synthesis, 7-153
vs neural control, 9-121
Control, humoral
of sleep and wakefulness, 9-142
of thermal exchange, 9-136
Control, neural
hierarchy of levels, 9-15
local processes, 9-11
of locomotion, 9-96
of movement, 9-96
of movement, cortical control, 9-112
of posture, 9-88
of skeletal muscle, 9-66 ff
of swallowing, 2-96
of sweating, 9-131
of thermal exchange, 9-128 ff
of urinary tract, 5-50 ff
of ventilation (schema), 6-46
priority and compromise, 9-17
resume of deficits, 9-161 ff
setpoint of, 9-19
vs endocrine control, 9-121
Control points in purine synthesis, 1-150
Control systems in genetics, 1-136
Control systems, summary of, 9-121 ff
Control, transmission of, 9-11
Control vs regulation, 9-18
Convergence
in depth perception, 8-119
in spinal cord, 9-71
Convulsions
from irritation of area 4, 9-115
in water intoxication, 4-117
origin of, in epilepsy, 9-172
Coombs test, 4-50
Copper injures basal ganglia, 9-99
Copper transport in plasma, 4-6
Coproporphyrins, 4-42
Core enzyme of polymerase, 1-170
Cori cycle of lactic acid, 7-135
Coriolis acceleration, 8-54
Cornea, 8-70
Coronary artery
blood flow, 3-131 ff
collateral circulation, 3-143
drugs vs collateral circulation in occlusion of, 3-144, 145
stimulation of collateral circulation, 3-145
Corpus callosum, function of, 9-119
Corpus luteum, 7-101
Cortex (see Adrenal cortex, Cerebellar cortex Cerebral cortex, etc)
Corti, organ of, 8-17
Cortical inhibitory mechanism, 9-145
Corticipetal fibers, 9-52
Corticobulbar tract, 9-27
Corticofugal fibers, 9-51
Corticospinal tract, 9-27
origin, areas 4 and 6, 9-113
Corticosteroid biosynthesis, 7-50
defect in congenital adrenal hyperplasia, 7-67
scheme of pathways for, 7-52
Corticosteroids (see also glucocorticosteroids)
assay of, 7-53
metabolism of, 7-53
physiological effects, 7-56
Corticotrophin releasing factor (CRF), 7-20
Cortisol (see also glucocorticosteroids)
actions of, 7-57
biosynthesis of, 7-51
Cortisol and cortisone metabolism, 7-54
Countercurrent system
and urea excretion, 5-36
of renal tubules, 5-20 ff
Counterpulsation, coronary blood flow, 3-154
Counterrolling of eyes, 8-52
Covalent backbone of DNA, 1-158
Covalent bonds in protein, 1-122
^{51}Cr for platelet turnover rate, 4-74
Cranial nerves
autonomic components, 9-57
classification of, 9-31 ff
visceral components, 9-54
Craniosacral system, 9-53
Creatine phosphate
cardiac muscle contraction, 3-40
in muscle, 1-96
Creatinine and renal dysfunction, 5-38
Creatinine clearance, 5-8, 39
Cremasteric reflex, 9-165
Crenation of erythrocytes, 4-31
Cretinism, 7-41
CRF (corticotrophin releasing factor), 7-20
Critical frequency of fusion, 8-110
Critical temperature, 9-131
Cross-bridges in muscle, 1-76
in sliding filament theory 1-72
Crossed extensor reflex, 9-73
Crossmatching, for blood transfusion, 4-53
Crossover of genes, 1-162
Crush syndrome and renal failure, 5-43
CSF (see Cerebrospinal fluid)
Cupula, vestibular, 9-42
Current, electrical
as stimulus to nerve, 1-38
during voltage clamping, 1-47
in activation of muscle, 1-89
Cushing effect, 3-179
Cushing's syndrome, 7-64
Cutaneous touch sensation, 8-147
Cyanide as poison, 6-78
Cyanide causes hypoxia, 6-63
Cyanocobalamine (see Vitamin B_{12})
Cyanosis, 6-78 ff
definition, 6-64
from defects in heart, 6-76
in bronchial asthma, 6-72
in emphysema, 6-74
in pneumonia, 6-69
Cycle of granulocyte turnover, 4-68
Cycle of lymphocytopoiesis, 4-93
Cycles
female reproductive, 7-101
photochemical, 8-82
Cyclic AMP
activates lipases, 7-129
and insulin secretion, 7-80
and phosphorylase system, 7-119
as purine derivative, 1-142
as second messenger, 7-5
hepatic, effect of glucagon, 7-85
in action of TSH on thyroid cells, 7-36
in catabolite repression, 1-190
in control of protein synthesis, 7-150
in PTH action on bone, 7-45
in secretion of calcitonin, 7-47
increases gluconeogenesis, 7-139
intermediary in action of catecholamines, 7-73
listing of actions, 7-6
mediates ACTH action on adrenal, 7-60
mediates vasopressin activity, 7-27
membrane receptor sites for, 1-6
role in glucogen synthesis, 7-117
stimulates hormone secretion, 7-21
Cylindruria, 5-42
Cystic duct, 2-72
Cystinuria, 1-140
Cytochrome oxidase, 6-78
Cytochrome system in muscle, 1-102
Cytosine, 1-142

Damping of neural circuit, 9-102
Dark adaptation
and receptive fields, 8-89
mechanisms of, 8-100
Dead space
anatomical vs physiological, 6-20
measurement, 6-20, 21
Deafness
categories of, 8-38
causes of, 8-33 ff
diagnosis of, 8-35 ff
treatment of, 8-34
Deamination, oxidative, 1-132

Decarboxylation of amino acids, 1 132
Decerebrate animal, 9-69
Decerebrate rigidity, 9-91
Decerebrate rigidity in man, 9-166
Decerebration, effect on respiratory centers, 6-42
effect on stretch reflexes, 2 72
Decibel notation for sound, 8-11
Decompression chamber and hypoxia, 6 65
Decompression sickness, 6-68
prevention by oxygen, 6-82
Decortication, 9 94
Decortication in man, 9 166
Defecation, 2-119
Defects, optical, 8 68
Deficits, anemias, 4-31 ff
Deficits, endocrine
diabetes mellitus, 7-87
goiter, 7 37
hyper-, hypothyroidism, 7-40 ff
hypophysectomy, protein metabolism, 7-147
of adrenal medulla, 7-75
of adrenocortical function, 7 63
of calcium homeostasis, 7-48 ff
of neurohypophysis, 7-28
releasing factors in therapy, 7-20
Deficits, genetic
aminoacidopathies, 1-135
anemia, 4-20
chronic granulomatous disease, 4 72
congenital adrenal hyperplasia, 7 66
disaccharide intolerance, 2-88
DPG deficiency (see also G6PD), 4 44
errors of metabolism, 1-136
erythroblastosis fetalis, 4-51
G6PD deficiency, 4-29
hemoglobinurias, 4-59
hemophilia, 4-76
of blood clotting, 4-79 ff
of purine, pyrimidine metabolism, 1 153
porphyrias, 4-47
proteinopathies, 1 135
sickle cell anemia, 4-37
spherocytosis, 4-36
thalassemia, 4-36
Deficits, metabolic
genetic basis, 1-136
proteinopathies, 1-135
Deficits, neural, 9-4
hypotheses concerning recovery, 9-6
recovery in cerebral cortex, 9-88
significance of level, 9-161
signs vs symptoms, 9 4
Deficits, neural, clinical, 9-161 ff
Bell's palsy, 9-37
facial paralysis, 9-36
of esophageal motility, 2-102
of swallowing, 2-97
of trigeminal pathways, 9-35
Parkinson's disease, 9-101
spastic hemiplegia, 9-116
spinal cord syndromes, 9-162
Deficits, neural, experimental, 9-5
after cerebellar operations, 9-97
after cortical lesions, 9-113
after lobectomy, lobotomy, 9-118
cerebral decortication, 9-94
cerveau and *encephale isole,* 9-139
from orbitofrontal ablation, 9-117
Deficits, neural, sensory
color blindness, 8-114
in visual system, 8-78
of hearing, 8-33 ff
of olfaction, 8-141
of vestibular function, 8-62
spinal cord lesions, 9-25
Degenerate nature of genetic code, 1 176
Degeneration of nerve fibers, 1-31
Deglutition (see also swallowing), 2-95
Degradation of protein, 7-148
Dehydration of body, 4-116
Dehydrogenase activity, 1-133
Deiodinase, thyroid, 7-33
Deiodination of thyroid hormones, 7-34
Deiter's nucleus, 9-45
Delay, synaptic, central, 9-75
Delayed response, 9-155
Deletion causes mutation, 1-185
Denaturation of protein, 1-127
Dendrites, 1-30
Denervation of muscle, 7 147
Densitometry, microspectral, 8-82
Deoxycorticosterone action in kidney, 5 10
Deoxyribonuclease, 1 151
Deoxyribonucleic acid (see DNA)
Deoxyribonucleotide, 1-146
Deoxyribose in DNA, 1 142
Depolarization of nerve fiber, 1-38
Deprivation, visual, 8-95
Depth perception, 8-117
Dermatomes, 9-23
Dermographism, 3-215
Desoxycorticosterone action in kidney (see Deoxycorticosterone action in kidney) 5-10
Detection, thermal, hypothalamic, 9-135
Detectors (see also Baroreceptors, Chemoreceptors, Mechanoreceptors, etc)
Detectors, neural, 9-1
Detrusor muscle of bladder, 5-49, 55
Deuterium oxide, absorption of, 2 84
Developmental physiology of vision, 8-95
Dexamethasone, 7-56
Dextran filtered in kidney, 5-5
Dextran for plasma volume, 4 119
Diabetes insipidus
and renal dysfunction, 5-47
and thirst, 2-7
from hypothalamic lesion, 9-167
pathogenesis, 7-28
Diabetes insipidus, nephrogenic, 5-46
Diabetes mellitus
clinical features, 7-87
control of ketogenesis in, 7-140
effect on glucose utilization, 7-122
lipid metabolism in, 7 131
Diaphragm, movement of, 6-28
Diarrhea, 2-119
dehydration from, 4-116
loss of bicarbonate ion, 4-109
with disaccharide intolerance, 2-88
Diathermy heating of hypothalamus, 9 134
Dichromats, 8-115
Dicumarol, clinical use of, 4-82
Dielectric constant of membrane, 1-15
Diencephalon, 9-39
components of, 9-20
Diet changes body water, 4-115
Differential thresholds, auditory, 8 31
Differentiation
affected by thyroid hormone, 7-38
in hemopoiesis, 4-15
of fast vs slow muscle, 1-111
of sexual anatomy and function, 7-88 ff
Diffusing capacity for CO, 6-26
Diffusing capacity for O_2, 6-24 ff
Diffusion, 1-17
calculation of rate, 1-19
facilitated, of glucose, 7-115
non-ionic, in kidney, 5 37
of carbon dioxide, 6 27
of gases, theory of, 6-3
Diffusion potentials, 1-33
Digital properties, neural, 9-13
Digitalis, effect on cardiac output, 3-119
Dimer of thymine, 1-168
Dinitrophenol action in kidney, 5 15
Dinitrophenol vs thyroid hormone, 7-39
Diodrast
in renal function tests, 5-39
secretion by tubules, 5 13
use in measurement of blood f, 3 160
Diaphasic action potential, 1-41
Dipolar nature of amino acids, 1 119
Direct inhibition
in spinal reflexes, 9-79
origin and significance, 1 55
Disaccharidases, 2-88
Disaccharide intolerance, 2-88
Discrimination (see name of discrimination)
Discrimination learning, 9 154
Discrimination of frequency, 8-15
Discrimination threshold for frequency, 8-32
Disease (see name of disease, or organ or system affected)
Disparity, retinal, 8-120
Disseminated (multiple) sclerosis, 9 170
Dissociation curves (see also oxyhemoglobin dissociation curves)
carbon dioxide, 6-16
combined, CO_2 and O_2, 6-71
oxygen, 6-11 ff
Dissociation of amino acids, 1-120
Disulfide bridges
in denaturation of ribonuclease, 1 128
in insulin molecule, 7-76
Diuresis, 5 18 ff
and urea excretion, 5 35
osmotic, 5-25
Diuretics, 5-26
Diuretics, mercurial, 5-15
Dizziness, 8-59
DNA, (see also Nucleic acid)
discovery of, 1-158
role in cardiac hypertrophy, 3-45 ff
DNA and genes, 1 136
DNA and mutations, 1-138
DNA ligase, 1-166
DNA molecules
genetic organization of, 1 162
single stranded, 1-166
size and shape, 1-161
structure of, 1-158
DNA of nucleolus, 1-6
DNA polymerase, 1-166
DNA replication, 1-163
and corticosteroid actions, 7-57
and granulocytopoiesis, 4-66
and lymphocytopoiesis, 4-93
folic acid requirement for, 4 38
in cycle of hemopoiesis, 4-13
in erythropoiesis, 4-22
regulated by steroids, 7-7
stimulated by androgen, 7-99
DNA replication time, 4-14
DNA structure, 1-142
DNA vs. RNA, 1-142
Dominance in genes, 1-136
Dominant hemisphere
lateralization of function, 9-120
localization of speech mechanisms, 9-148
Donath-Landsteiner hemolysin, 4-59

Donnan ratio and CO_2 transport, 6 18
Dopa and dopamine biosynthesis, 7-71
Dopa for Parkinson's disease, 9-101
Dopamine
and gonadotropin secretion, 7-15
as transmitter, 1 59
distribution in CNS, 9-83
in basal ganglia, 9-101
Dopamine-β-oxidase, 9 62
Dorsal root potentials, 9-11
Dorsal roots, visceral afferents in, 9-54
Dorsal spinocerebellar tract, 9-25
Dorsomedial thalamic nuclei, 9-39
Double helix, structure of, 1-60
Downhill vs uphill transport, 1-22
DPG (2,3-diphospho D-glyceric acid)
binding to hemoglobin, 4-44
concentration in stored blood, 4 55
Drinker respirator, 6-84
Drinking
control of, 9-125
rhythm of, 9-103
Drug effects
cause edema, 4-89
emetics, 3-110
in epilepsy, 9-172
in motion sickness, 8-61
on bone marrow, 4-19
on capillary permeability, 4-87
on colonic motility, 2-119
on gallbladder, 2 77
on gastric secretion, 2-45
on granulocytopoiesis, 4-71
on H^+ concentration, 4 104
on liver function, 2-67
on secretion of saliva, 2-29
on taste, 8-131
Drugs excreted by kidney, 5-37
Dubin-Johnson syndrome, 2-67
Ducts, salivary, 2 17
Ductus arteriosus
failure to close, 6-77
fetal circulation, 3-238 ff
Ductus venosus, age of closure of, 3 239
Duodenal loops, 2-113
Duodenal motility, 2 111
Duodenal rhythmicity, 2 113
Duodenal ulcer, 2-45
Duration of visual perception, 8-112
Dwarfism
pituitary, 7-143
thyroidal, 7-41
Dyads of retina, 8-75
Dynamic state of body constituents, 4-7
Dynamic vs static receptors, 8-44
Dysarthria, 9-150
Dysbarism, 6-68
Dysphagia, 2-103
Dyspnea, 6-59 ff
from defects in heart, 6-76
miscellaneous causes, 6-61

Ear and hearing, 8-12 ff
Early receptor potential, 8-86
Edema, 4-88 ff
cardiac, with renal dysfunction, 5-44
caused by aldosterone, 5-47
in renal dysfunction, 5-43 ff
nephrotic, 5-42
pulmonary, with dyspnea, 6-60
Edema fluid, 4-84
Edinger-Westphal nucleus, 9-32
EDTA and Ca binding, 7-44
EDTA-like relaxing factor, 1-94
EDTA prevents clotting, 4-76
EEG (see electroencephalogram)
Effective renal plasma flow, 5-15
Effectors, neural, 9-1
Efferent auditory pathways, 8-28
Efferent cochlear bundle, 9-37
Efferent nerve fibers, 9-74
in olfactory system, 8-138
in visceral system, 9 54
in visual system, 8-80
to inner ear, 8-25
to vestibule, 8-47
Efficiency of ventilation, 6 37
Einthoven method of vector analysis, 3-66
Eisenmenger's complex, 6 77
Elastic element
parallel, in muscle, 1 65
series, in muscle, 1-81
Elastic tissue of lung, 6-75
Elasticity of muscle, 1 79
Electrical properties
of cell membranes, 1-15
of living systems, 9-12
of muscle fiber membrane, 1 92
Electrical recording, 9 9 ff
Electrical stimulation, 9 8 ff
during conditioning, 9-152
in study of sensation, 8-5
of olfactory receptors, 8 135
of otolith system, 8 50
of salivary secretion, 2-27
of taste receptors, 8 130
self-stimulation of brain, 9-154
Electrical transmission, 1 59
Electrical vs chemical transmission, 9-82
Electrocardiogram, 3-64 ff
abnormalities of, 3-69 ff
digitalis effect on, 3 73
effect of myocardial injury on, 3-62
electrodes for standard leads, 3-67
left bundle branch block effect on, 3 72
myocardial ischemia effect on, 3 72
procaine amide effect on, 3-73
quinidine effect on, 3-73
right bundle branch block effect on, 3-69
time intervals during cardiac cycle, 3-104
vector analysis, 3 65 ff
ventricular hypertrophy effect on, 3 69
Electrocardiography, 3-58 ff
Electrochemical potential
in active transport, 1-21
in carrier transport, 1-21
Electroconvulsive shock and memory, 9-158
Electrode potentials, 1-33
Electrodes for electromyography, 1-106
Electrodermal response to hearing, 8-36
Electroencephalogram (EEG), 9-106 ff
activation of, 9-137
of sleep, 9-137
Electrolyte concentrations
in bile, 2-60
in blood plasma, 4-2
in gastric juice, 2-36
in lymph, 4-85
in pancreatic juice, 2-50
in perilymph, endolymph, 8-18
in saliva, 2-22
in succus entericus, 2-80
Electrolyte depletion
in Addison's disease, 7-63
in adrenal hyperplasia, 7-68
with water depletion, 4-116
Electrolytes
affect aldosterone secretion, 7-63
and membrane potentials, 1-35
intestinal absorption, 2-85
pancreatic secretion of, 2 53
taste of, 8-121
transported in gallbladder, 2-74
Electromagnetic radiation spectrum, 8-64
Electromyography, 1-104 ff
Electron microscopy of membranes, 1-3
Electron microscopy of muscle, 1-63 ff
Electron transport
in HCl secretion, 2 40
in mitochondria, 1-11
in nerve, 1-51
in phosphorylation in muscle, 1 102
Electrophoresis of plasma proteins, 4-4
Electrophysiology of reflexes, 9-74
Electrophysiology of sensation, 8-3
Electroretinogram (ERG) 8-86
Electrostatic bond hypothesis of muscle, 1 78
Electrotonic potentials (see also potentials, electrotonic), 9-11 ff
Elongation of polypeptides, 1 179
Embden-Meyerhof pathway in RBC, 4-28
Embolus following thrombosis, 4-80
Embryology
of nervous system, 9 20
of sarcoplasmic reticulum, 1-70
sexual differentiation, 7-92
Emetics, 2-110
Emotion, 9-143 ff
and gastric secretion, 2-47
Emphysema, 6-73 ff
changes in lung volumes, 6 72
detection of uneven ventilation, 6-21
dyspnea in, 6-59
volume-flow relations, 6-34
Encephale isole, 9-139
End plate of muscle, 1-57
End plate potentials
and acetylcholine release, 1 57
and quanta of acetylcholine, 1-89
as computational process, 9 13
Endocochlear potential, 8 22
Endocrine glands, 7-1 ff
neuroendocrine relations, 7 2
Endocytosis as transport, 1-6
Endocytosis in thyroid cells, 7-33
Endogenous sources of amino acids, 1-130
Endolymph, 8-40
electrolytes of, 8-18
Endometrium, cycles of, 7-102
Endonuclease, 1-151
Endoplasmic reticulum (ER), 1-7
Energy balance, 2-1
hypothalamic control of, 9-127
Energy exchange of nerve, 1-51
Energy generation in muscle, 1-96 ff
Energy of radiation, 8-64
Energy release in muscle, 1-104
Energy reserves in adipose tissue, 7-123
Energy requirements for vision, 8 84 ff
Energy sources for muscle, 7-112
Energy sources in man, 7-125
Energy transmission in hearing, 8-15
Enterogastric reflex, 2-10
and gastric emptying, 2-109

Enterogastrone
and gastric emptying, 2-109
and gastric secretion, 2-41
inhibits gastric secretion, 2-44
Enterohepatic circulation
of bile pigments, 2-68
of bile salts, 2-63
Enterokinase, 2-51
Environment, rotation of, 8-54
Enzyme action
in energy generation in muscle, 1-98
in fibrinolysis, 4-77
in membrane transport, 1 4
in mitochondrial membrane, 1-12
in phagocytosis, 4-63
in protein degradation, 7-149
Enzyme control, types of, 7-114
Enzyme deficit in gout, 1-155
Enzyme deficit in orotic aciduria, 1-156
Enzyme induction and repression, 1-187
Enzyme induction by steroids, 1-193
Enzyme pathways
for blood clotting, 4-75 ff
for glycogen synthesis, 7-117
for lipid synthesis, 7-124
for protein synthesis, 1-174
for purine synthesis, 1-147
for pyrimidine biosynthesis, 1-145
for RNA biosynthesis, 1-170
for synthesis of catecholamines, 7-71
in amino acid metabolism, 1-132
in control of lipogenesis, 7 141
Enzyme reactions and odor perception, 8-143
Enzyme recognition site, 1-174
Enzyme secretion by pancreas, 2-54
Enzymes (see also name of enzyme)
disaccharidases, 2-88
in gastric juice, 2-37
in pancreatic juice, 2-51
in saliva, 2 24 ff
in succus entericus, 2-82
Eosinophils of blood, 4 62
effect of cortisol on, 7-58
Ephapse, 1-59
Epilepsy
clinical description, 9-170 ff
effect on EEG, 9-108
irritation of area 4, 9-115
Epilepsy, psychomotor, 9-147
Epinephrine, 7-71
activation of phosphorylase, 7-118
and regulation of body temperature, 9-136
as autonomic transmitter, 9-62 ff
as insulin antagonist, 7-86
causes paralytic secretion of saliva, 2-26
conjugation and inactivation, 9-63
effect on cardiac output, 3-118
effect on gluconeogenesis, 7-137
effect on heart muscle, 3-116
in pheochromocyte, 7-73
increase in coronary blood flow, 3-138
released by acetylcholine, 9-61
renal blood flow effects of, 3-236
Equal-loudness contours, 8-32
Equivalent electrical circuit
for EPSP, 1-54
for muscle membrane, 1-91
of nerve fiber, 1-39
Endoplasmic reticulum (ER), rough and smooth, 1-8
Errors, translational, protein synthesis, 1-177
Erythroblastosis fetalis, 4-51
Erythrocyte defects, 4-34
Erythrocyte destruction, 4-34 ff
Erythrocyte dimensions, 4-32
Erythrocyte life span, 4-30
hemoglobin turnover, 4-36
Erythrocyte membrane
in hemolysis, 4-57
pores in, 1-17
water permeability, 1-27
Erythrocyte precursors, 4-24
Erythrocyte sedimentation rate, 4-60
Erythrocytes
cell indices, calculation, 4-31
deformability of, 4-61
destroyed in spleen, 4-35
formation in bone marrow, 4-11
hemoglobin as buffer, 4 105
in blood gas transport, 6-13 ff
intracorpuscular defects, 4-36
lifespan in stored blood, 4-54
metabolic pathways, 4-27
structure and function, 4-26 ff
variations in, 4 30
Erythron, defined, 4-25
Erythropoiesis, 4-21 ff
effect of cortisol, 7-58
from common stem cell, 4-18
regulation of, 4 25
steady state model, 4 26
suppression by hemoglobin, 4 23
Erythropoietic factor, renal, 4-26
Erythropoietin, 4-25
Esophageal sphincter
lower, 2-102
upper, 2-98
Esophagogastric junction, 2-102
Esophagus
and swallowing, 2 95 ff
disturbances of motility, 2-102
motility of, 2-100
pain from, 2-104
spasm of, 2-103
stricture of, 2-103
Essential amino acids, 1-129
Esterification in lipid synthesis, 7-127
Estrogen
adrenal synthesis of, 7-51
effect on LH secretion, 7-106
in reproductive cycle, 7-102
mechanism of action, 7-107
model of cellular action, 7-7
transport and metabolism, 7-106
Estrogen secretion
by human placenta, 7-110
in male, 7-101
in phases of ovarian cycle, 7-105
Ethyl alcohol
and vestibular function, 8-60
effect on gastric secretion, 2-46
Ethyl iodide, arteriovenous, measurement of cardiac output, 3-159
Eukaryotic cells, chromosomes of, 1-193
Eustachian tube and deafness, 8-34
Evans blue for plasma volume, 4-118
Evaporation of water for heat loss, 9-130
Evoked potentials, cortical, 9-105
Evolution of active transport, 1-24
Evolution of blood, etc., 4-1
Evolution of membranes, 1-16
Evolution of plasma proteins, 4-4
Exchange transfusion, 4-51
Excitation-contraction coupling, 1-95 ff
Excitation in retina, 8-89
Excitation of muscle, 1-61 ff
Excitation of nerve, 1-43
Excitatory postsynaptic potential (EPSP)
and chloride ions, 9-78
in spinal reflexes, 9-76 ff
origin and significance, 1-52 ff
Exercise, hyperpnea during, 6-57
Exocrine glands, control of, 9-53 ff
Exocytosis
as transport process, 1 6
in anterior pituitary cells, 7-11
Exogenous sources of amino acids, 1-129
Expeditions, high altitude, 6-65
Expiration
control of, 6 41 ff
movements of chest, 6-28 ff
pressure changes, 6 34 ff
pressure volume relations, 6-37
volume changes, 6-30 ff
Expiratory center
location, 6-43
recording activity from, 6-45
Expiratory reserve volume, 6-31
Extensor reflexes, decerebrate, 9-91
Exteroceptors, 8-1
Extracellular fluid, 4-113
Extracellular vs intracellular H^+, 4-110
Extraocular muscles, 8-75
Extrinsic factor in pernicious anemia, 4-37
Eye (see also Visual system), 8 70
anatomy of, 8-70
optical properties, 8-66 ff
Eye color, genetics of, 1 136
Eye movement, 8-96
from vestibular stimulation, 8-51

F-actin, 1-65
Facial nerve, autonomic outflow, 9-57
Facial nerve (VII), 9 35 ff
taste fibers in, 8-126
Facial paralysis, 9 36
Facilitated diffusion of glucose, 7 114
Facilitation, neural, 9 4
in spinal reflexes, 9 76
Factors, official names
in blood clotting, 4-75
Facultative water reabsorption, 5-19
Fallot, tetralogy of, causes hypoxia, 6-77
Fasting
control of ketogenesis in, 7-140
lipid metabolism in, 7-131
water retention in, 4-116
Fat, absorption of, 2-91
Fat excreted in feces, 2-57
Fat tissue, circulation at rest vs maximum dilatation, 3 166
Fatigue in cochlea, 8 21
Fatty acid CoA, 7-128
Fatty acid metabolism, 7 123 ff
Fatty acid oxidation cycle, 1 132
Fatty acid synthesis, 7-123
Fatty acids
affect initiation of peptide chains, 7-153
as insulin antagonists, 7-86
hepatic ketogenesis from, 7-140
in membrane structure, 1-16
oxidation inhibits glycolysis, 7-120
sources for lipid synthesis, 7 128
stimulate gluconeogenesis, 7 138
Fava beans and anemia, 4-29
Fecal fat excretion, 2-57
Feces, composition of, 2-120
Feces, defecation of, 2-119
Feedback control
of ACTH secretion, 7-61
of anterior pituitary cells, 7-22
of cochlear mechanics, 8-13
of granulocytopoiesis, 4-70
of hypothalamic secretion, 9-124

of neurohumoral systems, 7 14
of pyrimidine biosynthesis, 1-145
of thyroid gland, 7-36
vestibular, for movement, 8-40
Feedback loop, 9-18
Feeding (see also Food intake)
Feeding center, hypothalamic, 2-2
Feeding reflexes, 2-3
Fenestration for deafness, 8 34
Fenn effect in muscle, 1-86
Ferrihemoglobin (see Methemoglobin), 4-46
Ferritin, 4 39
Fetal circulation, defects related to hypoxia, 6-76
Fetal hemoglobin dissociation curve, 6-12
Fetoplacental unit, 7-109
Fetuin, 4-6
Fetus, blood flow in, 3-238 ff
Fever as set point change, 9-136
FFA of plasma, 7-123
Fibrin in blood clotting, 4-77 if
Fibrinogen, 4-75
as coagulant, 4-82
conversion to fibrin, 4-77
variations in plasma levels, 4-7
Fibrinolysis, 4-77
Fick method for measurement of blood flow, 3-158 ff
Fick principle for renal blood flow, 5-15
Filaments of muscle, 1-62
Filling of stomach, 2-107
Filtration, glomerular, 5-4 ff
filtration fraction, 5-15
measurement of rate, 5-4 ff
of protein, 5-41
First breath of newborn infant, 6-40
Fissures of cerebellum, 9-43
Flagella and cilia, 1-13
Flavoprotein enzymes in muscle, 1 102
Flexion reflex, 9-70 ff
Flicker fusion frequency, 8-110
Flocculonodular lobe
anatomy of, 9-46
functions of, 9-98
Fluoride ion in saliva, 2-23
Fluoroscopy of stomach, 2-107
Flux, transmembrane, 1-18
Flux, unidirectional vs net, 1-25
Folates prevent anemia, 4-38
Folding protein theory, 1-72
Folia, cerebellar, 9-45
Follicle, ovarian, cycle of, 7-101
Follicle-stimulating hormone (see also FSH)
action on ovary, 7-102
control of testis tubules, 7-99
Food as source of water, 4-114
Food intake
control of, 2-1 ff
factor in energy balance, 9-127
rhythmicity of control of, 9-103
Foot, cutaneous blood flow in, 3-214
Foramen ovale, patent
causes hypoxia, 6-77
Force in muscle contraction, 1-73
Force-velocity relationship in muscle, 1-84
Form discrimination, 8-108
Formylation of amino acids, 1-179
Fovea of retina, 8-73
Fragility of RBC, 4-58
Free water clearance, 5-22
Freeze-etch technique, 1-4
Freezing of stored blood, 4-54
Frequency coding, auditory, 8-27
Frequency discrimination, 8-15
Frequency discrimination threshold, 8 32
Frequency modulation, neural, 9 103
Frequency of nerve impulses, sensory, 8 7
Frequency of sounds, 8-11
Frequency response of ear, 8-32
Frequency selectivity, 8-28
Frohlich's syndrome, 2-2
Frontal eye fields, 9-117
Frontal lobe syndrome, 9-118
FSH secretion
control by steroid levels, 7-105
Functional residual capacity of lung, 6-31
Fundic glands of stomach, 2 32
Fundus of stomach, motility of, 2-104
Fusion of cells, 1-193

γ-Aminobutyric acid, 9-82
as transmitter, summary of, 1-59
γ Efferent system, 9 84
γ-Globulin, 4-7
γ Motor fibers, 9-83
in decerebrate state, 9-93
G-actin, properties of, 1-65
G6PD deficiency, in erythrocytes, 4 29
Galactose absorption, 2-86
Gallbladder
anatomy of 2-72
contractions of, 2-73
emptying, 2 76
functions of, 2-73
Gallstones, 2-77 ff
Galvani, Luigi, 9-9
Ganglia, autonomic, 9-55 ff
Ganglion (see also name of ganglion)
Ganglion cells in retina, 8-74
Gas (see name of specific gas)
Gas bubble, P-V relation, 6-39
Gas in intestine, 2-120
at high altitude, 6-67
Gases, techniques for measuring, 6-7 ff
Gases, theory and laws, 6-1 ff
Gases, transport by blood (see Carbon dioxide transport, Oxygen transport)
Gastrectomy for ulcer, 2 46
Gastric (see also Stomach)
Gastric distension
and food intake, 2 4
and water intake, 2-7
Gastric emptying, 2-108
Gastric filling, 2-107
Gastric fistula and food intake, 2-1
Gastric juice, 2-35 ff
Gastric motility, 2-104 ff
abnormalities of, 2-109
types of contractions, 2 105
Gastric pacemaker, 2-106
Gastric peristalsis, 2-106
Gastric secretion, 2-31 ff
control of, 2-41 ff
enzyme content, 2-37
HCl and electrolytes, 2 36
measurement of acidity, 2-47
normal course of, 2-44
phases of, 2-41 ff
Gastric secretory capacity, 2-45
Gastric ulcer and HCl secretion, 2-45
Gastrin, 2-15
effect on gastric secretion, 2-42 ff
in control of secretion, 2-41
Gastrocnemius, white muscle, 1-109
Gastrocolic reflex, 2-10
Gastroduodenal pressure cycle, 2-107
Gastroileal reflex, 2-116
Gastrointestinal (see also names of viscera, guts, etc)
Gastrointestinal gas at high altitude, 6 67
Gastrointestinal tract, circulation at rest vs maximum vasodilatation, 3 166
Gastrone, 2-38
Gay-Lussac's law of gases, 6-2
Gender recognition, 7-88
Gender role, 7-94
Gene activity, 1-187
and nucleic acids, 1 158
regulation of, 1-186
Gene expression, 1-193
Generation of neural signals, 9-16
Generator potential, sensory, 8 6
Genetic code, 1-175 ff
Genetic organization of DNA, 1-162
Genetic recombination, 1-162
Genetic sex, 7-88
Genetics of eye color, 1-137
Geniculate bodies (see Lateral geniculate body)
Geniculostriate bundle, 8-78
Genital ducts, differentiation, 7 92
Genital dystrophy, hypothalamic, 9-167
Genital sex differentiation, 7-92
Genitalia, differentiation of, 7-93
Genotype governs controls, 1-136
Genotype vs phenotype, 1-137
Geometric horopter, 8-120
Giant edema, 4-5
Gigantism, 7-143
Glands (see also Endocrine glands, Exocrine glands, or name of gland)
salivary, 2 17
Glands of small intestine, 2-79
Glands of stomach, 2-31
Glia cells
functions of, 1-31
varieties of, 9-16 ff
Globin
bilirubin binding, 2-65
structure of, 4-42
Globin variants, 4-45
Globulins, immunoglobulins, 4 101
Globus pallidus, 9-50
effect of lesions, 9-100
signs of lesion, 9-161
Glomeruli, renal
filtration in, 5-4 ff
filtration of Na^+, 5-24
filtration of protein, 5 41
measurement of filtration, 5-6 ff
structure, 5-1
Glomerulonephritis, 5-40
edema in, 5-44
Glomerulotubular balance, 5-12
Glossopharyngeal nerve (IX), 9-37
autonomic outflow, 9-57
taste fibers in, 8-126
to salivary glands, 2-20
Glucagon
as gastrointestinal hormone, 2 15
biosynthesis of, 7-78
chemical nature, 7-78
control of secretion of, 7-76 ff
Glucagon action
in hepatic cells, 7-85
increases cyclic AMP, 7-80
increases gluconeogenesis, 7-136
Glucocorticosteroids (see also Cortisol, Corticosteroids)
as insulin antagonists, 7-86
biosynthesis of, 7-51
control of synthesis, 7-60
increase lipolysis, 7-130
protein catabolic effect, 7-135

Gluconeogenesis
in adipose tissue, 7-127
irreversible steps, 7-132
pathways and control, 7-132
regulated by glucagon, 7-85
Gluconeogenesis vs lipogenesis, 7-140
Glucoreceptors, hypothalamic, 2-5
Glucose
intestinal absorption, 2-86
precursor for lipid synthesis, 7-123
stimulates insulin release, 7 79
Glucose-activation unit, 7 112
Glucose-6-phosphate dehydrogenase (see G6PD)
Glucose tolerance test
influence of growth hormone, 7-146
oral vs intravenous, 7-81
Glucose transport
by facilitated diffusion, 7-114
by renal tubules, 5-9 ff
inhibited by growth hormone, 7-145
passive, in muscle, 7-114
Glucose utilization
by erythrocytes, 4-29
by heart muscle, 7-121
energy generation in muscle, 1-97
energy yield of reactions, 1-104
Glucostatic hypothesis, 2-5
Glucuronyl transferase, 2-66
Glutamic acid as NH_2 donor, 1 134
Glutamine and gout, 1-156
Glutamine as source of NH_3, 5-31
Gluteal reflex, 9 165
Glycerinated muscle, 1-93
Glycerol in fat absorption, 2-92
Glyceroneogenesis, 7-127
Glycine in bile salts, 2 62
Glycogen homeostatic unit, 7-112
Glycogen metabolism in muscle, 1 97
Glycogen phosphorylase, 7-117
Glycogen synthesis, 7-117
Glycogenic amino acids, 1-132
Glycogenolysis
and energy generation, 1-98
regulated by glucagon, 7-85
Glycolysis in erythrocytes, 4-29
Glycolysis in muscle, 1-97
control of, 7-112
details of enzymatic processes, 1-99 ff
irreversible steps, 7-132
Glycolysis in nerve, 1 50
Glycolytic unit, 7-112
Glycoproteins of plasma, 4-4
Glycosuria
in acromegaly, 7 144
renal, 5-46
Goiter, 7-37
Goldman equation, 1-36
Golgi apparatus
and pancreatic secretion, 2 55
of anterior pituitary cells, 7-11
of neurons, 1-29
of thyroid gland, 7-29
structure and function, 1-10
Golgi tendon organs, 9-84
Gonadal sex differentiation, 7-91
Gonadotrophin release, cycles of, 7-94
Gonadotrophin releasing factor, 7 19
Gonadotrophs of anterior pituitary gland, 7-9
Gout, 1-153
Graded potential, 8-6
Gradient, intestinal, 2-112
Grand mal epilepsy
clinical description, 9-171
EEG pattern, 9-108
Graft rejection, 4-98
Graft vs. host reaction, 4-19
Granulocyte turnover rate, 4-66
Granulocytes, 4-62 ff
circulating in blood, 4 67
Granulocytic leukemia, 4 71
Granulocytopoiesis, 4-64 ff
from common stem cell, 4 18
hazards of chemotherapy, 4 71
Granulomatous disease of childhood, 4 72
Grasp reflex, decorticate, 9 94
Grasping movements, 9-116
Graves' disease, 7-40
Gravity on otoliths, 8 49
Gravity, zero
adaptation to, 8-54
test for vestibular function, 8 49
GRF (Growth hormone releasing factor), 7-19
Growth
abnormalities of, 7 143
affected by thyroid hormone, 7-38
cellular processes of, 7-146
hormonal control of, 7-143 ff
stimulated by androgen, 7 99
Growth hormone (GH)
amino acid sequence, 7 144
as insulin antagonist, 7-86
chemical nature, 7-143
localization in cells, 7 12
standard curve, assay of, 7 4
Growth hormone action, 7-143
increases glucose output from liver, 7-135
increases lipolysis, 7 130
like insulin action, 7-144
mobilizes lipid, 7 146
on glucose transport, 7 145
Growth hormone releasing factor (GRF), 7 19
Growth rate in hemopoiesis, 4-15
Guanine, 1 142
Guanylic acid, 1 149
Gustatory nucleus, 9 38

Habituation, vestibular, 8-54 ff
Hair cells
auditory, 8-21
for touch, 8-150
of saccule, 8 46
of utricle, 8-44
vestibular, 8 42
Haldane method
gas mixtures analysis, 6 7
sampling of alveolar air, 6-4
Hand, cutaneous blood flow in, 3-214
Haptoglobins, 4 6
Hashimoto's disease, 7 41
Head, Sir Henry, and aphasias, 9 149
Hearing, 8-10 ff
cortical localization of, 9-120
Hearing aids, 8-39
Hearing and speech, 8-29
Hearing, binaural, 8-28
Hearing deficits, 8 38
Heart (see also Myocardial, Myocardium)
absolute refractory period, 5-53
action potential, 3 52, 3-93
adrenal medullary catecholamines in regulation of, 3-115
anatomy, 3-25
anxiety effect on volume output, 3-118
aortic coarctation effects on circulation of, 3-138
arrhythmias, 3-75 ff
atrial contraction, 3-104
atrial fibrillation, 3 81 ff
atrial flutter, 3-80 ff
atrial systole, 3-103
atrioventricular block, 3-85
atrioventricular node, 3-56
autoregulation, rate and rhythm effects on, 3-110 ff
baroreceptor reflexes and venoconstriction, 3 180, 181
blood circulation of, 3-130 ff
blood supply to, 3-131 ff
blood volume during contracture, 3-98
bypass procedures for blood flow, 3-154, 155
calcium ion in excitation-contraction of, 3-36 ff
cardiac cycle sequence, 3-101 ff
cardiac massage, 3-153
chemoreceptor reflexes, 3 181 182
circulation in anemic states 3 138
conductance velocity 3 54
conduction system 3 54
contraction force, 3-87, 88
coronary artery collateral circulation, 3-143 ff
development of collateral circulation to, 3 143
diastasis, 3 103
dilatation, 3-43
effective refractory period, 3 53
electrophysiology, 3-48 ff
embryonic differentiation of myocytes of, 3 35
equilibrium in left and right chambers 3 124 ff
excitation contraction coupling, 3 36 ff
exercise effects on circulation of, 3 141, 142
extrasystoles, 3 77 ff
failure, 3-140
glucagon effect on regulation of 3 116
hypertension effects on circulation of, 3 141
hypertrophy, 3 41
hypothermic effects on circulation of, 3-140
impulse conduction after injury, 3 62
inferior cardiac nerve, 3 113
initiation of conductance impulse, 3-57
innervation of, 3-112, 113
internodal conduction of impulse, 3 55
isovolumetric contraction, 3 101
isovolumetric relaxation, 3 103
left ventricle reflexes, 3-185
maximum ejection, 3 101
measurement of output and work, 3 116 ff
mechanical activity, 3 86 ff
middle cardiac nerve, 3 113
muscle T tubules, compared with skeletal, 3 32
myocardial bundles of, 3 27
myocardial capillary circulation, 3 130
myocardial cells of, 3 28
myocardial tension, 3 110
myofilaments, 3-29 ff
nerves of, 3 113
nervous stimulation of blood flow in, 3-139
oxygen metabolism, 3-130
pacemaker cells, 3-28
pacemaker potential, 3-53
paroxysmal tachycardia, 3 79
percentage distribution of blood from, 3-2
phasic irregularity, 3-85
posture effect on volume output, 3-118
premature contractions, 3-77
protodiastole, 3-102
pulsus alternans, 3-84
pump action of, 3-98 ff
rapid filling, 3-103

reduced ejection, 3-102
reduced filling, 3 103
reflex effect on vasomotor tone, 3 184
regulation of, 3 110 ff
relative refractory period, 3-53
resting potential, 3-52
RNA in hypertrophy of, 3 46
sarcoplasmic reticulum, 3-31
sinoatrial block, 3-85
sinoatrial node, 3 55
sinus arrythmia, 3-84
sinus bradycardia, 3-85
sounds, 3-107 ff
spread of excitation impulse, 3-57, 58
stimulation of collateral circulation to, 3-145 ff
stress state response of, 3-136, 137
superior cardiac nerve 3-113
tachycardia, 3 137
temperature effect on autoregulation, 3 112
threshold potential, 3-50
transfusion effects on circulation of, 3 137
transmembrane potential, 3 48 ff
vagus nerve regulation of, 3-114
valves, movement during cardiac cycle 3-105 ff
valvular defect effects on circulation, 3-140
venoconstriction, 3-180, 181
ventricular fibrillation, 3-83
volume output, 3-118 ff
weight, percentage of body weight, 3-26
work of, and glucose utilization, 7-121
work of, effect on glucose entry, 7 116
work, power, and efficiency, 3 96 ff
workload in hypertrophy, 3 46

Heart defects, cause hypoxia, 6 77

Heart rate
aortic and atrial pressure, 3 11
at high altitude, 6-67
blood loss effect on, 3-186
cardiac reserve in, 3-129
carotid sinus pressure, 3-10
chemoreflex control of, 3-185
comparison of, during rest and exercise, 3-117
determination of steady state, 3-9
exercise and excitement effects on, 3-119 ff
nervous control of, 3-112
relation to carotid sinus pressure, 3-9
stress state effect on, 3-136
ventricular output control, 3 11

Heart ribosomes, control of aggregation of, 7-154

Heartburn, 2-104

Heat edema, 4 89

Heat loss, control of, 9-129

Heat of recovery in muscle, 1-87

Heat production
and temperature regulation, 9-131
by nerve fibers, 1-51
in skeletal muscle, 1-85

Heavy meromyosin (HMM), 1-67

Heavy water (see Deuterium oxide), 2-84

Helium in O_2 therapy, 6-82

Helix of myosin, 1-67

Hematurias, 5-40 ff

Heme-heme interaction, 4-43

Heme synthesis, 4-41

Heme synthetase, 4-42

Hemiplegia, levels of, 9-162

Hemiplegia, spastic, 9-116

Hemisection of spinal cord, 9-25

Hemochromatosis, 4-40

Hemocytometer, 4-32

Hemodynamics, 3 22

Hemoglobin, 4-41 ff
abnormal, 6-12
as buffer for H^+, 4-105
binding to organic phosphates, 4 44
binding with oxygen, 4-43
changes at high altitude, 6-66
component chains, 4 42
effect on erythropoiesis 4-23
fetal, 6 12
filtered in glomeruli, 5 4
hemes and O_2 transport, 6 17
in cyanosis, 6-79
isohydric shift, 6 17
oxygen capacity of, 6-6

Hemoglobin and bile pigments, 2-65

Hemoglobin degradation, 4-35

Hemoglobin derivatives, 4 46

Hemoglobin variants, 4-36 ff
and globin variants, 4-45
component chains of, 4 42
in sickle cell anemia, 4 37

Hemoglobinopathies, 4-45

Hemoglobinurias, 4-59

Hemolysis, 4 57
and jaundice, 2 67
and suspension stability, 4-57 ff
in stored blood, 4 55
in vivo, 4-59
normal and abnormal, 4-34

Hemolysis vs hemopoiesis, 4-36

Hemolytic anemia and G6PD, 4 29

Hemolytic disease of newborn, 4-51

Hemophilia, 4-79
deficiency of blood clotting, 4-76

Hemopoiesis, 4-10 ff

Hemopoiesis vs hemolysis, 4-36

Hemorrhage
causes vasopressin release, 7-26
hemostasis following, 4 73
physiological changes following, 4 120
water and electrolyte movements, 4-117

Hemostasis, 4 73 ff

Henderson-Hasselbalch equation
and CO_2 transport, 6-6
and H^+ in urine, 5-28
and plasma buffers, 4-104
calculations from, 4 112
for amino acid buffers, 1-118
nomogram for, 4-111

Heparin, 4-77
clinical use, 4-82

Hepatolenticular degeneration, 9-168
ceruloplasmin deficiency, 4-6

Hereditary orotic aciduria, 1-156

Hering-Breuer reflex, 6-47 ff
in pneumonia, 6-72

Hernia, hiatal, 2-103

Heteroplastic hemopoiesis, 4-13

Heterozygous state, 1-136

Hexokinase deficiency in RBC, 4-44

Hexokinase in muscle, 7-117

Hiatus hernia, 2-103

Hierarchy of neural controls, 9-15

High altitude
acclimatization, 6-66
and erythropoiesis, 4-26
hypoxia, 6-65

High pressure breathing, 6-83

Hippuric acid excretion, 5-13

Hiroshima nuclear bomb, 4-62

His, bundle of, 3-56

Histamine
and inflammation, 4-64
effect on cardiac output, 3-118
effect on gastric secretion, 2-45
relation to asthma, 6-73

Histocompatibility antigens, 4-100

Histones as regulators, 1-193

Hodgkin-Huxley equivalent circuit, 1-36

Hodgkin-Huxley theory of action potential, 1-48 ff

Hoffmann's reflex, 9-87

Holger-Nielsen resuscitation, 6 83

Holoenzyme of polymerase, 1-170

Homeostasis, 9-58
of body fluids, 4-1
of calcium, 7-42 ff
of triglycerides, 7 126

Homoiothermic animals, 9-128

Homoplastic hemopoiesis, 4-12

Homozygous state, 1-136

Hopping reactions, 9-114

Horizontal cells of retina, 8 75

Hormone secretion, 7-21

Hormone-sensitive lipase, 7 129

Hormone synthesis, 7-22

Hormones, 7-1
assay of concentrations, 7 3
control lipid metabolism, 7-130
control lipolysis, 7 130
gastrointestinal, 2 15 ff
general mechanisms of action, 7-5
localization by immunohistochemical methods, 7-10
synthesis vs release, 7 3

Hormones in lactation, 7-109

Hormones of pregnancy, 7-107

Horopter, geometric, 8-120

Horsley-Clarke technique, 9 5

Human chorionic gonadotropin (HCG), 7-108

Human voice in communication, 8-29

Human vs animal sensory studies, 8-4

Hunger, 2-1 ff
and insulin secretion, 7-84

Hunger contractions, 2-4
as type II waves, 2-105

Huntington's chorea, 9-170

Hydrochloric acid
in gastric juice, 2 36
measurement of, 2-47
mechanism of secretion, 2-38
secretion by parietal cells, 2 34

Hydrogen bond in base pairing, 1-151

Hydrogen bonds in DNA, 1-124

Hydrogen bonds in protein, 1 123

Hydrogen ion activity
and multiple factor theory, 6-56
disturbances of regulation, 4-106 ff
effect on Hgb-O_2 binding, 4-43
effect on respiration, 6 56
in extracellular fluids, 4-103
in fluids of body, 4-104

Hydrogen ions
and acidification of urine, 5-27
and signal generation, 9-16
buffer systems, 4-104
chemodetection, central, 6-47
excretion and fixation of, 4-104
form NH_4^+ in kidney, 5-31
metabolic sources of, 4-103
secreted in stomach, 2-39
sensitivity of central detectors, 6-53

Hydrogen sulfide and hemoglobin, 4-47

Hydrolysis of triglyceride, 7-127

Hydrophilic groups in membrane, 1-15

Hydrophilicity and diffusion, 1-19

Hydrophobic bonds in protein, 1-125

Hydrophobic groups in membrane, 1-15

Hydrostatic pressure in kidney, 5-6

Hydroxy-amino acids, 1-133

17-Hydroxycorticosteroids, 7-55
1-Hydrozinophthalazine, renal blood flow effects of, 3-236
Hyperactivity, hypothalamic, 9-142
Hyperaldosteronism, 7 70
Hyperalgesia, 8-156
Hyperbaric oxygen chamber, 6-22
Hypercalcemia and calcitonin, 7-48
Hypercapnia in asphyxia, 6-64
Hypercortisolism, 7-66
Hypermetropia, 8-69
Hyperphagia, hypothalamic, 2-2
and rage responses, 9-144
Hyperplasia as growth process, 7-146
Hyperpnea during exercise, 6-57
Hyperpolarization, neural, 1-38
in retinal units, 8-88
Hypersensitivity, delayed, 4-98
Hypersexuality, 9-146
Hypertension
coronary blood flow in, 3-141
in adrenal hyperplasia, 7-69
in glomerulonephritis, 5-40
in nephrosclerosis, 5-41
Hyperthyroidism, 7-40
Hypertonic fluids, 4-122
injection of, 4-116
Hypertrophy as growth process, 7-146
Hyperuricemia in gout, 1-153
Hyperventilation
causes alkalosis, 4-109
effect on alveolar air, 6-5
Hypnotoxin, 9-142
Hypochromic anemias, 4-32
Hypogammaglobulinemia, 4-102
Hypoglossal nerve, 9-38
Hypoglycemia
effect on food intake, 2-4
effect on gastric secretion, 2-46
stimulates GH secretion, 7-143
stimulus for glucagon release, 7-80
Hypophosphatemia, renal, 5-46
Hypophysectomized animal, 7-60
Hypophysectomy, 7-147
medical, 7-23

Loven reflex, 3-180
Lower motor neurons, 9-161
LTH secretion, control of, 7-15
Luminance thresholds, 8-103
Lung
alveolar air, 6-4
alveolar gas exchange, 6-13
blood pressure and flow regulation, 3-204
compliance, 6-31
exercise effects on circulation in, 3 208
fetal blood flow in, 2 239
gas diffusion in, 6-4 ff
gas exchange schema, 6-22
hysteresis in pressure-volume, 6-39
in pneumonia, 6-70
mechanoreceptors, 6-48
phasic blood flow, 3-206
physical model of alveoli, 6-39
pressure pulse in circulation, 3-206
pressure-volume relation, 6-32
pulmonary vessel reflexes, 3-184
respiratory effects on blood pressure and flow, 3 207
sheet flow concept of circulation in, 3 207
surface activity, 6-38 ff
vascular blood flow resistance in, 3-205
vascular waterfall concept of circulation, 3 207
vasomotor control of circulation in, 3 209
Lung volumes, 6-30
changes in asthma, 6 72
changes in emphysema, 6-74
changes in pneumonia, 6 71
effect of pressures upon, 6-31
measurement of subdivisions 6 31
Lupus erythematosus of kidney, 5-40
Lutein, ovarian, 7-102
Luteinizing hormone (see LH)
Luteotropic hormone (LTH), 7-15
Lymph, 4-3
and fat absorption, 2-92
composition of, 4-85 ff
from salivary glands, 2-20
lymphocyte content, 4-95
production and flow rates, 4 86
Lymph nodes
and lymph flow, 4 84
migration of lymphocytes, 4 97
Lymphatic, cannulation of, 4 97
Lymphatic obstruction and edema, 4-89
Lymphatic system, 4-83 ff
Lymphocyte flow, 4 99
Lymphocyte karyotypes, 7-89 ff
Lymphocyte pool, 4-97
Lymphocyte transforming factor, 4-98
Lymphocytes, 4-92 ff
circulation and migration, 4-96
role in immune response, 4-100
Lymphocytic leukemia, 4-10
Lymphocytopoiesis, 4-93
Lymphoreticular system, 4-90 ff
Lymphotoxin, 4-99
Lysosomes
as cell organelles, 1-10
degrade protein, 7-148
of granulocytes, 4-62
Lysozyme
in gastric juice, 2-38
in saliva, 2-24

M, N and P antigens, 4-51
Macrocytic anemias, 4-33
Macromolecules and pinocytosis, 1-25
Macula adherens, 1-14
Magenstrasse, 2-107
Magnesium ions
and ATPase activity of myosin, 1-93
and phosphorylase system, 7-119
Malate cycle in lipogenesis, 7-126
Malate in gluconeogenesis, 7-133
Male estrogen secretion, 7-101
Malnutrition causes edema, 4 89
Maltose, absorption of, 2-88
Mammary glands, 7 109 ff
Mammary myoepithelial cells, 7 28
March hemoglobinuria, 4-59
Marrow transplantation, 4 18
and lymphocytopoiesis, 4-95
Masking of sounds, 8-32
Mastication, 2-95
Maturity-onset diabetes, 7-87
Maximal tension in muscle, 1-83
Maze learning, 9-155
Mechanoreceptors (see also Baroreceptors)

Pentose phosphate pathway, 7-126
Pepsin in gastric juice, 2-37
Pepsinogen cells of stomach, 2-31
Peptidase, pancreatic, 2-52
Peptide bond formation, 1-180
Peptide bonds in protein, 1-121
Peptide chain initiation, 1-179
control of, 7-153

Peptide chain termination, 1-181
Peptide chains in ribosomes, 7-152
Peptides
absorption of, 2-90
in protein synthesis, 7-148
Perception of depth, 8 117
Perception of rotation, 8-53
Perceptual duration, visual, 8-112
Pericardium, anatomy, 3-27
Perilymph
and sound transmission, 8-14
electrolytes of, 8-18
Periodic breathing, 6-58
Periodicity in muscle fibers, 1-64
Peristalsis
esophageal, 2-100
gastric, 2 106
Peristalsis in small intestine, 2 113
Permeability coefficient, 1-18
Permeability of membrane
change during nerve impulse, 1-49
of muscle fiber, 1-93
of nucleus, 1-7
Permease, 1-139
in sugar transport, 1-5
Pernicious anemia, 4-33
and gastric secretion, 2-38
pathogenesis, 4-37
Peroxidase in thyroid gland, 7-32
Peroxisomes and ER, 1-11
Perspective, visual, 8-117
Petit mal epilepsy, 9-171
EEG pattern, 9-108
Phage, RNA sequences, 1-178
Phagocytosis by granulocytes, 4-62
Phantom limb, 9-167
Pharyngeal peristalsis, 2-101
Phases of gastric secretion, 2-41 ff
Phases of ovarian cycle, 7 104
Phenotype vs genotype, 1-137
Phenylketonuria (PKU), 1-141
Pheochromocytoma, 7-75
Philadelphia chromosome in leukemia, 4-19
Phillipson's reflex, 9-73
in decerebrate posture, 9 92
Phloridzin, effect on blood glucose, 7-83
Phlorizin, and glucose transport in kidney (see also Phloridzin), 5-10
Phosphate
and acidification of urine, 5-30
binding to hemoglobin, 4-44
in renal dysfunction, 5-47
PTH and exchange in bone, 7-45
PTH and renal loss of, 7-45
source of H^+, 4-103
transport in kidney, 5-13
Phosphate bond energy
and fat absorption, 2-91
and HCl secretion, 2-40
and muscle contraction, 1-96
Phosphate buffer system, 4-105
Phosphate transport in plasma, 7-43
Phosphaturia, 7-45
Phosphocreatine in muscle, 1-96
Phosphodiesterase
in second messenger theory, 7-5
relation to lipolysis, 7-129
Phosphofructokinase, 7-120
Phosphogluconate pathway, 4-28
Phospholipids in membranes, 1-16
Phosphorus of plasma, 4-2
Phosphorylase, 7-118
Phosphorylases of muscle, 1-99
Phosphorylation
and energy release in muscle, 1-102
and thyroid hormones, 7-39
in activation of lipase 7-130
in control of lipogenesis, 7-141
Phosphorylation of ADP, 1-95
Phosphorylation of glucose
blocked by growth hormone, 7-145
in muscle, 7-116
Photochemistry of vision, 8-81
Photoelectric oximetry, 6-10
Photometric units, 8-65
Photons, 8-64
Photopic curve of luminosity, 8-65
Photopigments, 8-84
Physics of sound, 8-10
Physiological capacity of bladder, 5-53
Pigment of eye, 8-70 ff
Pigmentation in Wilson's disease, 9-169
Pigmentation of skin and cyanosis, 6 81
Pigments of bile, 2-64 ff
Pigments of cones, 8-82
Pinocytosis, 1-25
in blood capillaries, 4-83
in intestinal absorption, 2-90
Pitressin
decrease in coronary blood flow, 3-139
renal blood flow effects of, 3 236
Pituitary-adrenal axis, 7-61 ff
Pituitary depletion assay, 7-16
Pituitary gland (see also Adenohypophysis, Neurohypophysis)
embryology of, 7 24
Frohlich's syndrome, 2-2
hypothalamic connections, 9-41
Pituitary-thyroid axis, 7-36
Placenta
blood flow in, 3-239
development of, 7-107
estrogen synthesis in, 7 110
lactogen secretion, 7-109
secretion of steroid hormones, 7-103
thyrotropin secretion, 7 109
Placing reactions, 9-113
Planes of semicircular canals, 8-41
Plantar reflexes, 9-164
Plasma
alkali reserve, 6-9
calcium concentrations, 7-43
composition of, 4-2
phosphate concentrations, 7-43
Plasma amino acids
affected by insulin, 7-84
effect on growth hormone release, 7-143
Plasma cells, 4-94
Plasma constituents (see also name of constituent)
and renal function, 5-8
in acid-base disturbances, 4 110
Plasma cortisol, 7-53
assay of, 7-53
Plasma flow, renal, 5-15 ff
Plasma iodine, 7-33
Plasma proteins, 4-3
and edema formation, 4-88
as buffer system, 4-105
binding to testosterone, 7-97
biosynthesis and dynamic state, 4-7
osmotic pressure, species comparison, 3-4
variations in, 4-6
Plasma steroid hormones, 7-103
Plasminogen vs fibrin, 4-77
Platelet formation, 4-18
Platelet transfusion, 4-74
Platelet turnover rate, 4-74
Platelets (see Blood platelet)
Pleated sheet structure of protein, 1-126
Pneumonia
lobar vs broncho-, 6-69
oxygen therapy in, 6-81
Pneumotaxic center, 6 45
location, 6-42
Pneumothorax
effect on interpleural pressure, 6-38
effect on mechanoreceptors, 6 48
Poikilothermic animals, 9 128
Poiseuille's law, 3-23, 24
Poisoning
carbon monoxide, 6 78
cyanide, 6-78
Polar conduction in intestine, 2 115
Polar properties of protein, 1-126
Polarization pattern in saccule, 8-48
Polarography for O_2 tension, 6-10
Polycythemia, 6-80
Polymerase
for RNA synthesis, 1-171
in synthesis of nucleotides, 1-150
Polymerization of actins, 1-65
Polymers in cells, 1-1
Polypeptides
assembly into proteins, 1-183
elongation of, 1-179
Polyribosomes and mRNA, 1-182
Polyuria, 5-42
Pool, motor neuron, 9-71
Pools of amino acids, 1 131
Pools of blood granulocytes, 4-67
Pores in membrane
and transport rate, 1 4
of erythrocyte, 1-17
Porphyrias, 4-47
Porphyrin enzymes, 4 39
Porphyrin of hemoglobin, 4-41
Porphyrin synthesis, 4-41
Porphyrins from hemoglobin degradation, 4-35
Portal system, hypothalamico-hypophysial, 7-13
Position in space and vestibular function, 8-40
Positive control by operon, 1 189
Positive pressure breathing, 6-49
Postcentral gyrus, 9-109
Posterior lobe of cerebellum, 9-43
Posterior lobe of pituitary gland (see also Neurophyophysis), 7-24 ff
Posterior roots, spinal, 9 23
Postganglionic fibers, 9-55 ff
peripheral distribution, 9-56
Postsynaptic inhibition, 9-79
Post-translational controls of genes, 1-192
Postural reflexes, 9-95 ff
Posture
and stretch reflex, 9-72
as rhythmic mechanism, 9-102
control of, 9 88 ff
Potassium current
during action potential, 1-49
transmembrane in muscle, 1-92
Potassium depletion in alkalosis, 4-110
Potassium equilibrium potential, 1-92
Potassium ions
active transport processes, 1-23
affect secretion of H^+, 5-34
aldosterone and tubular transport, 7-59
and cochlear potentials, 8-22
and Hodgkin-Huxley theory, 1-36
and hormone secretion, 7-21
and insulin release, 7-80
and transmembrane potential, 1-34
depletion, with polyuria, 5-42
in vestibular function, 8-40
renal transport, 5-26, 27

Potential (see also name of potential)
Potentials, electrical
and HCl secretion, 2-40
and neurosecretion, 7 14
and salivary secretion, 2-27

during stimulation of nerve, 1-40
of auditory hair cells, 8-19
volume conduction, 9 11
Potentials, resting vs action, 1-34
Potter turbinometer, measurement of blood flow, 3-155
Precentral motor cortex, 9-89
Prefrontal region, cerebral cortex, 9 117
Preganglionic fibers, 9-55 ff
Pregnancy
and Rh antigen system, 4-51
and steroid hormones, 7-103
effect on blood volume, 4-120
hormonal control, 7-107 ff
vomiting in, 2-110
Pregnenolone, 7-51
Preservation injury in blood, 4-53
Pressure, hydrostatic
and lymph formation, 4-85
and Starling principle in capillaries, 4-122
during swallowing, 2-99
gastroduodenal, 2-107
in ileum, 2-116
in urinary tract, 5-53
measurement in capillaries, 4-86
relations in kidney, 5-6
Pressure, osmotic, 1-27
and glomerular filtration, 5-6
and lymph formation, 4-85
and Starling principle in capillaries, 4-122
variations affect lymph flow, 4-87
Pressure-volume relation
for gas bubble, 6-39
for lung, 6-37
Pressures that move air, 6-34 ff
Pressures that move fluid, 4-123
Presynaptic inhibition, 1-56
in spinal reflexes, 9-80
Primaquine causes G6PD deficiency, 4-29
Primates, cortical lesions, 9-114
Priority in control systems, 9-17
Prism for light, 8-65
Problem-solving tests, 9-155
Progesterone
in ovarian cycle, 7-105
in synthesis of glucocorticoids, 7-51
metabolic pathways of, 7-104
secreted during pregnancy, 7-107
Progestin
in reproductive cycle, 7-103
mechanism of action, 7-107
transport and metabolism, 7-106
Proinsulin
model of protein assembly, 1 184
synthesis of, 7-77
Projectile vomiting, 2-110
Prolactin inhibitory factor (PIF), 7 15
uncertain chemical nature, 7 19
Proliferation, calculation of, 4-15
Promoter in operon, 1-189
Proprioceptors, 8-1
Prostaglandins and body temperature, 9-136
Prostate gland, androgen on, 7 99
Protein biosynthesis
affected by steroid hormones, 7-7
and memory trace, 9-159
and thyroid hormone action, 7-39
codons for, 1-175
function of RNA, 1-179
hormonal control of, 7 147
inhibition by antibiotics, 1-181
Protein biosynthesis in liver, 7-151
Protein-bound iodine (PBI), 7-34
Protein metabolism, 1-129
and adrenal hormone actions, 7-56
and gluconeogenesis, 7-136
hormonal control of, 7 147
Protein molecules
conformation of, 1-124
models for their assembly, 1-184
types of bonds in, 1-122
Protein sparing compounds, 1-130
Proteins
absorption of, 2-89
assembly from polypeptides, 1-183
classes of, 1-115
physicochemical properties, 1-121
summary of functions, 1-114
Proteins in bile, 2-69
Proteins in interstitial fluid, 4-85
Proteins in lymph, 4-85
Proteins in plasma (see also Plasma proteins), 4-3
Proteinuria
absent in pyelonephritis, 5-41
in glomerulonephritis, 5-40
in nephrosclerosis, 5-41
in nephrotic syndrome, 5 40
significance of, 5-41
Proteoses, absorption of, 2-90
Prothrombin, 4-75
Prothrombin time, 4-78
Protons (see also Hydrogen ions), 2-39
Protoporphyrin IX, 4-41
PRPP-amidotransferase, 1-147
PRPP in gout, 1-155
PSP (phenol red)
renal secretion, 5-13
test for excretion, 5-39
Psychological sex differentiation, 7-94
Psychomotor epilepsy, 9-171
Psychophysical study (see Techniques, psychophysical),
Pulmonary artery, "edge" pressure of, 3-206
Pulmonary blood vessels, reflex from distension of, 6-51
Pulmonary edema, dyspnea in, 6-60
Pulmonary veins, critical closing pressure of, 3-207
Pulmonary ventilation
abnormal patterns, 6-58
as rhythmic mechanism, 9-103
control of, as regulation, 9-125
efficiency, 6-37
first breath of infant, 6-40
hyperpnea during exercise, 6-57
hysteresis in curves, 6-38
interpleural pressures, 6-38
multiple factor theory of control, 6-56
pressure-volume relation, 6-37
pressures for air flow, 6-34 ff
range of normal values, 6-33
regulation of, 6-52 ff
regulation of $[H^+]$, 4-108
resistance to air flow, 6-35
significance of dead space, 6-20
total vs alveolar, 6-20
volume-flow relations, 6-34
work of breathing, 6-36
Pulmotor, 6-84
Pulvinar, 9-40
Pumps, ionic, in nerve, 1 49
Pupil
optics of, 8 67
properties of, 8-71
Purine derivatives, 1-142
Purine-pyrimidine pairing, 1-151
Purines
biosynthesis of, 1 147
deamination of, 1 134
degradation of, 1 151
in genetic code, 1 175
incorporation into nucleic acids, 1-150
reutilization of, 1-149
synthesis in gout, 1-154
Purkinje cells
conductance of impulse, 3-57
of cerebellum, 9-44
Purkinje fibers, transmembrane potential, 3-49
Puromycin
inhibits memory 9-159
inhibits protein synthesis, 1-182
Purpura, 4-80
Putamen, 9-50
Pyelonephritis, 5-41
Pyloric glands, 2-32
Pylorospasm, 2-109
Pylorus of stomach, 2-104
Pyramid of cerebellum 9-99
Pyrimidine derivatives, 1-142
Pyrimidines
biosynthesis of, 1 143
deamination of, 1-134
degradation of, 1-151
in genetic code, 1-175
incorporation into nucleic acids, 1 150
reutilization of, 1 149
Pyrogen
action on kidney, 5-16
on hypothalamus, 9-136
Pyruvate dehydrogenase
and control of gluconeogenesis, 7-138
in glycolytic unit, 7-120
Pyruvate oxidation, 1-103

Quadriplegia, 9-162
Quanta of radiation, 8-64
Quantal nature of transmission, 1-58
Quantum theory of light, 8 63
Quaternary structure of protein, 1-128

Radiation, heat loss, 9-129
Radioactive isotopes
Fe, Cr, for RBC volume, 4 119
for transmembrane flux, 1-25
^{131}I for plasma volume, 4-118
Radioautography
of anterior pituitary cells, 7-12
with tritiated thymidine, 4-13
Radioimmunoassay, 7-3
for ACTH, 7-62

Radioimmunoassay—*continued*
of calcitonin, 7-48
of corticosteroids, 7-54
of insulin, 7-76

Reflexes, feeding, 2-3
Reflexes, respiratory, 6-48 ff
cause of vasoconstriction in finger, 3-187
from baroreceptors, 6-48
from CO_2 detectors, 6-52
from H^+ detectors, 6-56
from low O_2 detectors, 6-54
from pulmonary vessels, 6-51
from thermoreceptors, 6-52
Hering-Breuer, 6-47
miscellaneous types, 6-51
pain, 6-51
Reflexes, spinal
during recovery from shock, 9-163
electrophysiology of, 9 74 ff
Reflexes, urinary, 5-51
Reflexes, visceral, 2-9 ff
Refraction of light, 8-64
Refractive index of eye, 8-66
Refractory periods
of muscle, 1-80
of nerve, 1-45
Refractory states and ion pumps, 1-50
Regeneration of nerve fibers, 1-31
Regional potentials, cochlear, 8-22
Regulation, 9-18
genetic, 1-186 ff
metabolic, 7-112
of acid-base balance, renal, 5-27 ff
of blood volume, 4-117
of body fluids, 4-115
of body temperature, endocrine, 9-136
of body temperature, neural, 9-128 ff
of erythropoiesis, 4-25
of granulocytopoiesis, 4-69
of $[H^+]$, 4-106
of platelets, 4-74
of sodium excretion, 5 24 ff
of ventilation, 6-52 ff
of ventilation during exercise, 6-57
schemata, 9-122
typical, 9-121
Regulation vs control, 9-18
Reinforcement in conditioning, 9-154
Reissner's membrane, 8-17
Rejection of grafts, 4-98
Relative refractory period
of muscle, 1-80
of nerve, 1-45
Relaxing factor, 1-93
Releasing factors 7 13
activity in human, 7-20
assay of, 7-15
chemistry of, 7-18
clinical significance of, 7-23
in blood of portal system, 7-13
mechanism of action, 7 20
REM (rapid eye movement), 9-138
Renal (see also Kidney, Glomeruli, Tubules, name of process, name of substance excreted)
Renal circulation, 3-227 ff
Renal erythropoietic factor, 4-26
Renal failure, 5-43
effect on acid-base balance, 4-106
Renal glycosuria, 5-46
Renal hypophosphatemia, 5-46
Renal tubular acidosis, 5-45
Renin
bioassay for, 7-62
control of Na^+ secretion, 5-25
Renin-angiotensin, vasoconstrictor effects of, 3-172
Renin-angiotensin system, 7-62
Rennin in gastric juice, 2-37
Renshaw cell inhibition, 1-57
in spinal reflexes, 9-81
Replicases for RNA, 1-171
Replication of DNA, 1-163
Replication of RNA, 1-169
Repression of enzymes, 1-187
Repressor vs inducer, 1-187
Reproductive cycle, female, 7-101
Residual volume of lung, 6-31
Resistance
to diffusion of CO_2 in lung, 6-27
to diffusion of O_2 in lung, 6-24
to pulmonary air flow, 6-35
Resonant frequency and odor, 8-143
Respiration (see also Inspiration, Expiration, Pulmonary ventilation)
Respiration, artificial, 6-84
Respiration, control of, 6-41 ff
multiple factor theory, 6-56
Respiration, muscles of, 6 28 ff
abdominals, schema of control, 6 51
maximal pressures developed, 6-33
Respiration, symbols used, 6 1 ff
Respirators, 6 84
Respiratory centers
automaticity of, 6-44
identification of, 6-42 ff
recording activity from, 6-45
Respiratory distress syndrome, 6-40
Respiratory gases (see also CO_2, O_2), 6-1 ff
Respiratory minute volume, 6 52 ff
Respiratory quotient
of nerve, 1-51
of salivary glands, 2-21
Respiratory rate vs dead space, 6-21
Respiratory reflexes (see Reflexes, respiratory)
Respiratory sinus arrhythmia, 3-187
Rest-length of muscle, 1-63
Restiform bodies, 9-46
Resting membrane potential, 1-89
Resting tension of muscle, 1-82
Resting vs action potentials, 1-34
Restraining mechanism, hypothalamic, 9-144
Resuscitation, 6-83 ff
Reticular formation, medullary, 9-31 ff
activating mechanism, 9-140
influence on visual system, 8-81
respiration, control of, 6-42 ff
Reticular formation, spinal, 9-22
Reticulocytes, 4-31
in erythrocytopoiesis, 4-24
Reticulospinal tract, 9-29
Reticulum
endoplasmic, 1-7
sarcoplasmic (see Sarcoplasmic reticulum)
Retina, 8-72
absolute sensitivity of, 8-84
distribution of rods, cones, 8-69
interaction of units, 8-87
organization of, 8-75
receptive fields, 8-89
receptive fields for color, 8-115
Retinal disparity, 8-120
Retinaldehyde, 8-82
Reverberatory network, 9-76
Reversion of mutation, 1-185
Reynolds' number, 3-7, 19
for air flow in lung, 6-35
Rh antigen system, 4-51
Rheological properties of blood, and suspension stability, 4-61
Rhinencephalon
and limbic system, 9-146
and olfaction, 8-138
Rhodopsin, 8-81
Rhythmic mechanisms, neural, 9-102
Rhythmic segmentation, 2-111
Rhythmicity of bowel, 2-113
Ribonuclease
denaturation of, 1-128
pancreatic, 2-52
Ribonucleic acid (see RNA)
Ribonucleotide biosynthesis, 1-146
Ribose in RNA, 1-142
Ribosomal RNA
and nucleolar function, 1-6
structure and function, 1-172
Ribosome cycle, 7-152
Ribosomes
aggregation of, 7-152

hormonal control of protein synthesis, 7-148
in hypophysectomy, 7-149
significance of RNA, 1 172
Ribs, in respiration, 6 29
Rickets, vitamin D resistant, 5-46
Rifamycin vs RNA synthesis, 1-171
Righting, natural, 9-96
Righting reflexes, 9 96
of decorticate animal, 9-94
Rigidity
decerebrate, 9-92
parkinsonian, 9-100
Rigor of muscle, 1-75
RNA (see also Nucleic acids)
messenger (see Messenger RNA)
role in cardiac hypertrophy, 3 45 ff
RNA and learning, 9-159
RNA biosynthesis, 1-169
and corticosteroid actions, 7-57
and thyroid hormone action, 7-39
in bone, 7 45
stimulated by androgen, 7-99
RNA molecules, 1-169
structure of single strand, 1-192
RNA of nucleolus, 1-6
RNA polymerase, 1-169
control via, 1-190
RNA replicases, 1-171
RNA sequences of phage, 1-178
RNA structure, 1-142
RNA vs DNA, 1-142
Rods vs cones
distribution of, 8-69
in dark adaptation, 8-101
microscopic anatomy, 8-74
Rollbewegungen, 2-114
Rossolimo's reflex, 9-87
Rotameter, measurement of blood flow, 3-155
Rotating environment, 8-54
Rotation, perception of, 8-53
Rough ER, 1-8
Round window, 8-14
Rubrospinal tract, 9-29
connections of, 9-50
Ruminants, urea cycle, 5-34

Saccadic eye movements, 8-97
Saccules, 8-46
Sacral autonomic outflow, 9-58
Saline infusions, 4-117
Saliva
composition, 2-22
functions, 2-28
Saliva and thirst, 2-6
Saliva, secretion of, 2-21
disturbances, 2-30
paralytic, 2-26
rate and volume, 2-22
Saliva spreading and heat loss, 9-130
Salivary enzymes, 2-29
Salivary glands, circulation at rest vs maximum vasodilatation, 3-166
Salivatory nuclei, fibers from, 9-57
Salivatory nucleus (inferior), 9-37
Salivatory nucleus (superior), 9-36
Salt (see Electrolyte, name of salt)
Salty taste, 8-122
Sarcolemma
relation to T tubule, 1-71
stimulation of muscle via, 1-90
Sarcomere
definition, 1-62
myocardial, 3-28 ff, 88 ff
Sarcoplasm of muscle, 1-62
Sarcoplasmic reticulum, 1-70, 3-31
as relaxing factor, 1-94
calcium storage and release, 3-36
concentration of calcium by, 1 90
stores calcium ions, 1 94
Satiety, defined, 2-2
Saturation of carrier transport, 1-20
Scarpa's ganglion, 8-49
Schafer's method, resuscitation, 6-83
Scholander method for gas analysis, 6 8
Schwann cells, 1-31
Scleroderma and dysphagia, 2-103
Sclerosis, disseminated, 9-170
Scotopic curve of luminosity, 8-65
Seasickness, 2-110
Second messenger theory, 7-5
Secondary sex characters, 7-94
Secretin, 2-15
and secretion of bile, 2-70
control of pancreas, 2 56
evokes insulin release, 7 80
test of pancreatic function, 2-57
Secretion
by colon, 2-82
by pancreas, 2-53 ff
by renal tubules, 5-13 ff
by small intestine, 2-79
gastric, 2-31 ff
gastric phases, 2-44
of bile, 2-60 ff
of glucagon, 7-79
of H^+ in kidney, 5-29
of HCl, 2-38
of insulin, 7-79
of saliva, 2-21
of saliva, disturbances of, 2-30
Secretion granules, anterior pituitary gland, 7-9
Secretory capacity of stomach, 2-45
Secretory vesicles, adrenal medulla, 7-72
Sedimentation of blood, 4-60
Segmental nerves, 9-23
Segmentation of bowel, 2-111
Seizures, epileptic, 9-172
Selectivity for frequency, 8-28
Self-stimulation of brain, 9-154
Semicircular canals, 8-41
Semilunar valves, closure, mechanism of, 3-107
Seminiferous tubules, 7-99
Semipermeable membranes, 1-28
Sensation
consciousness of, 8-2
in control of food intake, 2-4
visceral, and digestion, 2-10 ff
Sensitivity of receptors
auditory, 8-19
olfactory, 8-140
retinal, 8-84
thermal, 8-152
Sensorimotor cortex, cerebral, 9-110
Sensory changes in CNS lesions, 9-162
Sensory coding, 8-3
Sensory disabilities, 9-24
Sensory nerves, 9-74
Sensory pathways, 9-24 ff
Sensory processes, 8-1 ff
Sensory responses, neural, 8-6
Septal defects, cardiac, cause hypoxia, 6-77
Series elastic element, 1-81
Serotonin
and inflammation, 4-64
as transmitter, 1-59
distribution in CNS, 9-83
in small intestine, 2-80
Serous cells, salivary, 2-19
Sertoli cells, 7-100
Serum proteins, 4-4
Setpoint for body temperature, 9-136
Setpoint of control system, 9 19
Sex characters, secondary, 7-94
Sex chromosomes, 1 137
abnormal numbers of, 7-88
and sex differentiation, 7 88
Sex differentiation, 7-88 ff
stimulated by androgen, 7-99
Sham rage, 9 144
Shock (see also Spinal shock, etc)
cardiac blood flow during, 3-141
electric, and memory, 9 158
Shortening of muscle, 1 80
Shortening reaction, 9-92
Shunts, pulmonary, 6-22 ff
causes of hypoxia, 6-76
Sialorrhea, 2-30
Sickle cell anemia
abnormal hemoglobin, 4-31
as a proteinopathy, 1-138
hemoglobin variants, 4-37
Siggaard-Andersen nomogram, 4-112
Sign of Babinski, 9-161
diagnostic value, 9-164
Signal generation, neuronal, 9-16
Signals, neural, coding of, 9 12
Signet ring cells of anterior pituitary gland, 7-9
Signs vs symptoms, neural, 9-4
Silent period of reflex, 9-86
Silicone prevents clotting, 4-76
Silver chromate technique, 1-29
Single unit analysis, 9-10
of cochlear function, 8-24
of lateral geniculate body, 8-92
of olfaction, 8-135
of retinal interactions, 8-87
of taste, 8-127
Sinoatrial node, 3-55
Sinus node, heart, conductance velocity, 3-55
Skeletal muscle
arteriovenous anastomoses in, 3-222
blood circulation in, 3-217
blood pH effects on circulation, 3-218
bradykinin vasodilation effect in, 3-219
carbon dioxide effects on blood flow in, 3-218
circulation at rest vs maximum vasodilatation, 3-166
collateral blood flow, 3-222
contraction, compared with myocardium, 3-36
control of, 9-66 ff
exercise effect on blood flow in, 3-220
neural control of blood flow in, 3-217
reactive hyperemia, 3-221
red vs white, 9-90
tone of, 9-88
tone vs spasticity, 9-166
Skin
blood circulation in, 3-213 ff
central neural control of blood flow, 3-216
circulation at rest vs maximum dilatation, 3-166
dermographism, 3-215
dorsal root vasodilator fibers, 3-216
flare reaction, 3-214
flush reaction, 3-215
local edema, 3-215
red reaction, 3-215
venous circulation of, 3-214
wheal reaction, 3-215
white reaction, 3-215
Skin and touch sensation, 8-147

Skin pigment and cyanosis, 6 81
Skin temperature, 9-135
Sleep, 9 137 ff
  humoral control, 9-142
  paradoxical, 9 142
  significance of, 9-143
Sleeping sickness, 9-141
Sliding filament theory, 1 72
Slow muscle fibers, 1-110
Slow waves, EEG, 9-138
Small intestine
  nerve supply, 2-9
  secretion by, 2 79
Smell, 8-132 ff
Smooth ER, 1 8
Smooth muscle, control of, 9-53 ff
Smooth pursuit eye movement, 8 98
Snake venom and hemolysis, 4-60
Snellen chart, 8 107
Sodium chloride and thirst, 2-6
Sodium current
  during action potential, 1-48
  transmembrane in muscle fiber, 1-93
Sodium cyanide and respiration, 6-56
Sodium inactivation, 1-48
Sodium ions
  active transport processes, 1 23
  aldosterone and tubular transport, 7-59
  and glucose absorption, 2-87
  and Hodgkin-Huxley theory, 1-36
  and Meniere's disease, 8-61
  and size of action potential, 1-46
  in countercurrent system, 5-20
  renal transport, 5-23 ff
Sodium pump in nerve, 1 49
Soleus muscle, red, 1-109
Solubility coefficients of gases, 6-3
Somatotrophin (see Growth hormone, GH)
Somesthetic area, cerebral, 9-109
Somnolence, 9-141
  with hypothalamic lesion, 9-167
Sound
  physics of, 8 10
  stereophonic, 8-33
Sound level and deafness, 8-34
Sound localization, 8-33
Space station, 6-69
Spastic hemiplegia, 9-116
Spatial factors, visual, 8-105
Spatial modulation transfer function, 8-108
Spatial resolution in eye, 8-69
  and clarity of vision, 8-105
Spatial summation, 9-70
Specific dynamic action, 1-132
Specific gravity of urine, 5-21
Specific heat of blood, 4-1
Specific taste fibers, 8-126
Spectral luminosity function, 8-65
Spectral response function, 8-82
Spectrum of electromagnetic radiation, 8-64
Speech, 9-147 ff
Speech and hearing, 8-29
Speech audiometry, 8-38
Speech centers, 9-120
Speech disorders, 9-148
Spermatogenesis, 7-99
Spherical aberration, 8-67
Spherocytosis, hereditary, 4-36
Sphincter, esophageal
  lower, 2-102
  upper, 2-98
Sphincter of oddi, 2-75
Sphincters, urinary, 5-49
Spinal accessory nerve, 9-38
Spinal animal, 9-69
Spinal cord, 9 21 ff
  control of vasoconstriction, 3-168
  myelination of fiber tracts, 1-31
  neural tracts, 9-24 ff
  typical lesions, 9-162
Spinal nerve roots, 9-23
Spinal shock, 9-7
  effect on posture, 9-90
  stages of recovery, 9-162
Spinal state and posture, 9-90
Spinothalamic pathways, 9-25
Splanchnic circulation, 3 224 ff
Splanchnic nerves, 2-8
Splay of glucose titration curve, 5 12
Spleen
  and circulation of lymphocytes, 4-97
  blood flow, 3-225
  destruction of erythrocytes, 4-34
  forms bile pigments, 2 65
  in marrow transplantation, 4-18
Split-brain technique, 8-5
Spontaneous movement, 9-16
-S-S- bridges in insulin, 7 76
St Vitus's dance, 9 169
Standard reference levels for sound, 8-12
Stapes, functions, 8 14
Starling curves, cardiac output, 3-125
Starling principle (capillary), 4-122
  applied to glomeruli, 5-4
Starvation and gluconeogenesis, 7-134
Static reactions, neural, 9-95
Static vs dynamic receptors, 8-44
Statoconia, 8-44
Stem cell pool, 4-15
Stem cells
  in erythropoiesis, 4-21
  in granulocytopoiesis, 4-65
  in hemopoiesis, 4-12
Stepping, spinal, 9-103
Stereocilia
  auditory, 8-19
  vestibular, 8-42
Stereophonic sound, 8-33
Stereotaxic surgery, 9-5 ff
Steroid hormones
  enzyme induction by, 1-193
  of adrenal cortex, 7 50 ff
  of ovary, 7-103
  of testis, 7-95
  penetration of membranes, 7-5
Steroids (see Adrenal steroids, Ovary, Testis)
Sticky point in RNA, 1-180
Stiles-Crawford effect, 8-68
Stimulation (see Electrical stimulation, Thermal stimulation, etc.)
Stimuli, sensory, 8-1
Stimulus for olfaction, 8-132
Stimulus for pain, 8-154
Stimulus for touch, 8-145
Stomach (see also under Gastric)
  control of emptying, 2-108
  electrical activity of, 2-106
  glands of, 2-31
  motility of, 2-104 ff
  nerve supply, 2-9
Stop signals in RNA synthesis, 1-171
Storage compartment in hemopoiesis, 4-17
Storage of blood, 4-53
Strength-duration curve, 1-38
Streptomycin
  disturbs vestibular function, 8-61
  inhibits protein synthesis, 1-182
  resistance to, 1-182
Stretch reflex, 9-72 ff
  and muscle spindles, 9 82
  clinical use, 9-87
  in decerebrate state, 9-93
Striate cortex, 9-111
  visual functions of, 8 80
Striated muscle (see Muscle, skeletal)
Striations of muscle, 1-62
Stricture, esophageal, 2 103
Structural genes, 1-187
Strychnine and inhibition, 1-56
Subliminal fringe, 9-71
Subliminal stimulus for nerve, 1 37
Sublingual glands, 2-18
Submaxillary glands, 2-17
Submucous plexus, 2-8
Substantia nigra, 9-50
  dopa and melanine, 9-101
  effect of lesions, 9-100
Substrate availability, 7-134
Substrate oxidation in man, 7-125
Substrates for gluconeogenesis, 7-135
Subthalamic body (of Luys), 9-50
Succus entericus, 2-80
Suckling and oxytocin release, 7-27
Sucre piqûre, 9-65
Sucrose absorption, 2-88
Sudden death with asthma, 6-73
Sugars, transport into muscle, 7 115
Sulfate ion
  from amino acid metabolism, 1-131
  transport in kidney, 5 13
Sulfonamide drugs vs carbonic anhydrase, 6-17
Sulfonphthalein, renal secretion, 5-13
Sulfur containing amino acids, 1 133
Sulfur oxidation, 4-103
Summation
  in nerve, 1-39
  spatial, 9-70
  temporal, 9-76
Summation potential, cochlear, 8-22
Supplementary motor area, 9 113
Suppression of mutation, 1-185
Suppressor mechanism, hypothalamic, 9-141
Supraoptic nuclei, 7-25
Supraopticohypophysial tract, 7-28
Surface activity in lung, 6-38
Surgical procedures
  for deafness, 8-34
  in study of sensation, 8 5
  stereotaxic operations, 9-5
Surveillance, immune, 4-98

Thymine, 1 142
Thymine dimer formation, 1-168
Thymus
in immunity, 4-92 ff
migration of cells, 4-96
source of lymphocytes, 4-95
Thyroglobulin, 7-32
transportation through thyroid cells, 7-33
Thyroid binding, abnormal, 7 37
Thyroid C cells, 7 46
Thyroid colloid, 7-33
Thyroid deiodinase, 7-33
Thyroid disorders, 7-29
Thyroid gland, 7-29 ff
and regulation of body temperature, 9-136
control of function, 7-29 ff
Thyroid hormones
blocking of synthesis, 7-32
distribution and metabolism, 7-33
increase in coronary blood flow, 3-138
mechanisms of action, 7-38
stored as thyroglobulin, 7-32
synthesis, storage and release, 7-30
vs dinitrophenol, 7-39
Thyroid pituitary-axis, 7-36
Thyroid stimulating hormone (see TSH), 7-35
Thyrotrophs of anterior pituitary gland, 7-9
Thyrotropin (see TSH), 7-35
Thyroxin, 7-29
Tic douloreux, 9-35
Tickling, 8-157
Tidal volume of respiration, 6-31
changes in emphysema, 6-74
changes in pneumonia, 6-71
Tight junctions, 1-14
Tilt angle, threshold, 8-53
Time factors
vestibular, 8-53
visual, 8-110
Tinnitus with deafness, 8-35
Titratable acid of urine, 5-30

Titration curve
of amino acid, 1-119
of buffer systems, 4-104
renal absorption of glucose, 5-11
T_m for glucose, 5-10
Tolbutamide and insulin release, 7-80
Tolerance, immunological, 4-92
Tone of muscle, 9-89
Tone vs spasticity of muscle, 9-166
Tongue in taste sensation, 8-122 ff
Tonic innervation from cerebral cortex, 9-116
Tonic postural reflexes, 9 95
in decerebrate state, 9-91
Tonometers for blood gases, 6-8
Tonotopy of auditory system, 8-30
Total peripheral resistance, 3-23
Touch sensation, 8-145 ff
in gut, 2-10
Toxic nodule in thyroid gland, 7 41
Tracheobronchitis from O_2, 6-82
Tracts, neural (see also name of tract or pathway)
myelination of, 1-31
Tracts, spinal and brainstem, 9-24
Tractus solitarius
and facial nerve, 9-35
and nerve IX, 9-37
and nerve X, 9-38
receives taste fibers, 8-128
Transamination
in intestinal absorption, 2-90
of amino acids, 1-132
Transamination systems, 1-134
Transduction, neuroendocrine, 9-124
Transfer factor in immunity, 4-98
Transfer function
spatial modulation, 8 108
temporal modulation, 8-111
Transfer RNA (tRNA)
activation of amino acids, 1 173
and peptide chain initiation, 1 179
in control of protein synthesis, 7-149
Transferase, glycogen synthesis, 7-117
Transferrin, 4-39
Transferrin in plasma, 4-6
Transformation of bacteria, 1-163
Transfusion (see also Blood transfusion), 4-48
cardiac circulation effects of, 3-137
Transitions cause mutations, 3-183
Translational controls for genes, 1-191
Translocation, peptide synthesis, 1 181
Transmembrane potential (see also Membrane potential, Potentials), 1-34 ff
Transmission, chemical, 1-58 ff
CNS transmitters, 9-14
distribution of CNS transmitters, 9-83
in autonomic system, 9-59
in basal ganglia, 9-100
Transmission, electrical, 1-59
Transmission, electrical vs. chemical, 9 82
Transmission of sound, 8-10
Transmission, synaptic, 1-52 ff
Transplantation of cells, 4-19
Transport
by renal tubules, 5-8 ff
of amino acids, 1-139
of glucose, facilitated, 7-114
of plasma lipid, 4-4
of sugars into muscle, 7-115
Transport, active, 1-21
Transport, carrier-mediated, 1-20
Transport, uphill vs downhill, 1 22
Transverse gyrus of Heschl, 9 110
Transverse tubules
in activation of muscle fiber, 1-90
of twitch vs slow fibers, 1-111
ultrastructure of, 1 70
Transversions cause mutations, 1-183
Trapping of I^+ by thyroid, 7-30
Tremor
as rhythmic mechanism, 9-102
in cerebellar dysfunction, 9 97
of Parkinson's disease, 9-99
TRF (see alse TSH releasing factor), 7-16
Triad of sarcoplasmic reticulum, 1-70
Tricarboxylic acid cycle
and energy release in muscle, 1-101
in amino acid metabolism, 1-132
in mitochondria, 1-11
in nerve, 1-51
Triceps jerk, 9-87
Trichromacy, visual, 8-113
Trigeminal nerve (V), 9-33 ff
and oral sensation, 8-126
Trigeminal neuralgia, 9-35
Triglyceride absorption, 2-91
Triglyceride homeostasis, 7-126
Triglyceride lipase, 7-129
Triglycerides, 7-123
Triiodothyronine, 7-29
Triplet-degenerate code, 1-178
Tritiated thymidine
study of granulocytopoiesis, 4 66
study of hemopoiesis, 4-13
study of lymphocytopoiesis, 4-93
Trochlear nerve (IV), 9-32
Tropomyosin
concentration in myocardium, 3-32
interaction with actin and myosin, 3-38
Tropomyosin and troponin, 1-66
Troponin
concentration in myocardium, 3-32
interaction with actin and myosin, 3-38
Troponin and Ca ions, 1-66
Trypsin, pancreatic, 2-51
Trypsinogen, pancreatic, 2-51
Tryptophan and protein synthesis, 7-151
Tryptophan operon, 1-189
TSH releasing factor (TRF), 7-16
chemical structure, 7-18
synthesis and release, 7 36
TSH (thyrotropin), 7-35
control of secretion, 7-15
secreted by placenta, 7-109
Tuber cinereum, 9-41
Tubules, renal, 5-1 ff
ammonia excretion, 5-31
bicarbonate transport, 5-27 ff
chloride transport, 5-23 ff
excretion of drugs, 5-37
H^+ secretion, 5-29
measurement of function, 5-40
non-ionic diffusion, 5-37
obligatory vs facultative water reabsorption, 5-19
potassium transport, 5-26
reabsorption in, 5-8 ff
secretion by, 5-13 ff
sodium transport, 5-23 ff
Tumors of adrenal medulla, 7-75
Tuning of neural circuit, 9-102
Turnover of hemopoietic cells, 4-19
Turnover of protein, 7-147
Turnover of red cells, 4-24
Turnover rate of platelets, 4-74
Turnover time in erythropoiesis, 4-23
Twitch muscle fibers, 1-110
Two-neuron arc, 9-1
inhibition of, 9-80
Two-point threshold, 8-151
Tympanic membrane, 8 12
Tympanic temperature, 9-132 ff
Tyrosine
iodinated derivatives, 7 30
precursor for catecholamine biosynthesis, 7-71
precursor of thyroid hormones, 7-29
Tyrosine transaminase activity, 7 149

Ubiquinone in muscle, 1-102
UDPG pathway in muscle, 1-98
Ulcerative colitis, 2-117
Ultrafiltration, renal, 5-4
Ultrasound, measurement of blood pressure, 3-152
Unidirectional vs net flux, 1-25
Unit cell membrane, 1-3
Units of CHO metabolism, 7-112 ff
Units of light, 8 66
Unmyelinated fibers, 1-31
Uphill vs downhill transport, 1-22
Uracil, 1-142
Urea
conservation in ruminants, 5-34
excretion during diuresis, 5 35
in uremia, 5-46
induces denaturation, 1-128
renal excretion, 5-34 ff
Urea clearance, 5-39
Urea cycle, 1-153
Urease in gastric juice, 2-38
Uremia, 5-45, 46
Ureogenesis and glucagon, 7 85
Ureters, 5-48 ff
Urethra, 5-49
in micturition, 5-55
Uric acid
from degradation of purine, 1-151
transport in kidney, 5-13
Uridine-5'-monophosphate, 1-143
Uridine ribonucleotide, 1-144
Urinary bladder, 5-47
physiological capacity, 5-53
Urinary corticosteroids, 7-55
Urination, 5-54, 55
Urine flow
and osmolarity, 5-23
and solute excretion, 5-23
Urine formation, 5-1 ff
abnormalities of, 5-38 ff
acidification, 5-29 ff
control of specific activity, 5-21
hyper- vs hypotonicity, 5-20 ff
summary of processes, 5-3
urea excretion, 5-34 ff
Urine tests, 5-38 ff
Urobilin, 2-64
Urobilinogen, 2-64
Uropepsin, 2-37
Uroporphyrins, 4-42
Uterus, cycles in, 7-102
Utricles, 8-44
Uvula of cerebellum, 9-99

Vagus nerve, 9-37 ff
afferents affecting respiration, 6-48
and control of respiration, 6-43
and food intake, 2-4
and reflex vasopressin release, 7-26
autonomic outflow, 9-57
control gastric secretion, 2-35
control of hormone release, 2-16
in swallowing, 2-96
regulation of heart rate, 3-114
respiration after vagotomy, 6-45
taste fibers in, 8-126

to digestive tract, 2-8
to pancreas, 2-49
Vagusstuffe, 9-59
Valve, ileocecal, 2 116
van der Waal's bond in protein, 1-122
Van Slyke-Neill manometric apparatus, 6-9
Van Slyke volumetric apparatus, 6-9
Vascular tissue, anatomy, 3-164, 165
Vasoconstrictor fibers, 3-166 ff
Vasodilator fibers, 3 170, 171
Vasopressin (see also Antidiuretic hormone, ADH)
chemical structure of, 7-25 ff
control of release of, 7 25
neurosecretion of, 7-24
therapy of diabetes insipidus, 7-28
vasoconstrictor effects of, 3-172
Veins, pressure pulse of, 3-198
Velocity of light, 8-63
Velocity of sound, 8 10
Venoms cause hemolysis, 4-60
Venoms induce clotting, 4-82
Venous return, affects pulmonary ventilation, 6-49
Ventilation (see under Alveolar, Pulmonary ventilation)
Ventral nuclei of thalamus, 9-39
Ventral root potentials, 9-11
Ventral roots
spinal, 9-23
visceral fibers, 9 54
Ventral spinocerebellar tract, 9-25
Ventricles, heart
anatomy, 3-25
contraction, as determinant of venous blood pressure, 3-200
contraction force-velocity, 3-93 ff
conduction of impulse, 3-56
emptying, patterns of, 3-99 ff
equilibrium of left and right output, 3-124 ff
exercise effect on blood volume of, 3-119 ff
extrasystoles, 3-78
fibrillation, 3-83
pressure receptors, 3 185
pressure-volume during cardiac cycle, 3-105
transmembrane potential, 3-48
wall tension in contraction, 3-92
weight, 3-26
Vergence movement of eyes, 8-98
Vermis of cerebellum, 9-43
Vertigo, 8-59
Vesicles
embryonic brain, 9-21
membrane-delimited, 1-8
presynaptic, 1-52
Vestibular efferent system, 8-25
Vestibular function, 8-40 ff
Vestibular nerve, 8-49
cerebellar connections, 9-48
innervation of receptors, 8-46
Vestibular system
classes of responding cells, 8-58
control of eye movement, 8-98
electrical potentials in, 8-57
habituation in, 8-54
psychophysical study, 8-50
single units in brainstem, 8-58
temporal characteristics, 8-53
Vestibulocochlear nerve (VIII), 9-37
Vestibulospinal tract, 9 27
origin of, 8-49
Villi, intestinal, 2-114
Villikinin, 2-115
Virilization in adrenal hyperplasia, 7-67
Visceral motor areas, cerebral cortex, 9-116
Vis a tergo, pressure gradient in systemic circulation, 3-200
Visceral nerves, 9-54
Visceral nervous system (see also Autonomic nervous system), 9-53 ff
higher levels of control, 9-64
Visceral pain, 2-11 ff
Visceral reflexes to gut, 2-9
Visceral sensations from gut, 2-10 ff
Viscosity of blood, and suspension stability, 4-60
Vision, 8-63 ff
basic visual functions, 8-98 ff
energy requirements for, 8-85
photochemistry of, 8-81 ff
Visual acuity, 8-106
Visual cortex
activity of single units, 8-93
development of competence, 8-95
Visual deprivation, 8-95
Visual system
anatomy of, 8-70 ff
central pathways, 8 78
lateralization of function, 9-120
Visuosensory area, 9-111
Vital capacity, 6-31
at high altitude, 6-67
Vitamin B_{12}, 2-94
deficiency in pernicious anemia, 4-33
prevents pernicious anemia, 4-37
renal clearance of, 5-8
Vitamin D, 7-42 ff
question of renal action, 7-45
Vitamins, absorption of, 2-93
Vitreous humor, 8-72
Voice, communication via, 8-29
Voltage clamp technique, 1-47
Voluntary movement
and basal ganglia, 9-100
and cerebellum, 9-97
as rhythmic mechanism, 9-103
as signal generation, 9 16
Vomiting, 2-14
dehydration from, 4-116
mechanisms of, 2 110 ff
with intestinal obstruction, 2-116
von Békesy audiogram, 8-37
von Economo, Constantin, 9-104

Wakefulness, humoral control, 9-142
Waking state, 9-137 ff
Wallerian degeneration of nerve fibers, 1-32
Warm receptors, 8-153
Water (see also Water movement)
colligative properties, 5-17
distribution in body, 4-113
free water clearance, 5-22
heat loss in evaporation, 9-130
iceberg structure of, 1-123
structure of molecules, 1-16
Water balance, 4-114 ff
control of, 9-125
Water content of tissues, 4-114
Water depletion
and epileptic seizures, 9-172
causes, clinical features, 4 116
Water intake
and thirst sensation, 2-6
and water balance, 4-114
control mechanisms, 2-1
Water intoxication, 4-117
Water movement
in gastric secretion, 2-41
intestinal absorption, 2 84
obligatory vs facultative reabsorption, 5-19
osmosis, 1-27
permeability coefficient, 1-26
renal excretion, 5 17 ff
transmembrane, 1-17
Water output and balance, 4-114
Water retention in starvation, 4-116
Watson-Crick model of base pairs, 1-152
Watson-Crick model of DNA, 1-159
Wave on basilar membrane, 8 14
Wave theory of light, 8-63
Wavelength and color vision, 8-91
Wever-Bray phenomenon, 8-20
White blood cells (see name of cell, Granulocytes)
White muscle fibers, 1-109
White vs. red muscle, 9 90
biochemistry of, 7-112
Wilson's disease, 9-99
ceruloplasmin deficiency, 4-6
clinical description, 9-168
Wobble hypothesis for codons, 1 177
Wolf-Parkinson-White syndrome, 3-77
Wolffian duct, differentiation, 7-92
Work-induced growth, 7-147
Work of breathing, 6-36
Writing and speech, 9-148

X chromosome, 1-137
X-ray crystallography
of DNA fibers, 1-159
of nucleic acid crystals, 1-151
X-ray diffraction
of actin and myosin, 1-74
of membranes, 1-3
of peptide bond, 1-121
Xanthine oxidase, 1-152
Xanthinuria, 1-156
Xerostomia, 2-30

Y chromosome, 1-137

Z line, myocardial sarcomere, 3 30 ff
Zero gravity
adaptation to, 8-54
as test for vestibular function, 8-49
Zinc in insulin synthesis, 7-77
Zonula adherens, 1-14
Zwitterions, amino acids, 1-119
Zymogen granules, pancreatic, 2-54
